gas have become available, the interest in coal gasification has decreased considerably.

Petroleum-derived residues have gained some attention as feedstocks for gasification, with the increasing yield of residues in petroleum refining because of decreasing oil quality and the need for their economic and environmentally acceptable utilization, for example, for H_2 production. Use of *wood* as a feedstock has played a continuous role in small-scale gasification units (e.g., for the production of gaseous fuels) and more recently gained interest in the context of biomass energy applications.

Advances in gasification have been made possible by progress in other fields. Fundamental research on the mechanism and kinetics of chemical reactions, mass and heat transfer, fluid dynamics, and mathematical modeling has contributed to a better understanding of the phenomena occurring in gasification processes long after their successful operation started.

This chapter introduces fundamental aspects and process technologies of gas production from solid feedstocks. Given the variety of new developments in the past decades, only a selection can be presented here to help identify and discuss basic principles, state of the art, and future trends. For more details, the reader is referred to review articles on gasification fundamentals [50 – 52], gasification processes [53 – 59], or both [60, 61], and to numerous publications on this subject.

4.1. Fundamentals

Gasification of solid feedstocks involves the complex interaction of chemical reactions and physical processes such as heat and mass transfer.

Figure 18 shows a scheme of the main chemical reactions that occur when carbonaceous materials are exposed to reactive gases at high temperature. The yield and composition of the product are determined by the combined effects of feedstock properties and reaction conditions on the thermodynamics and kinetics of individual reactions. For example, the yields of liquid byproducts (e.g., tar, phenols) depend on the reaction conditions that prevail during pyrolysis and secondary reactions of the volatile products (e.g., temperature, gas-phase residence time).

4.1.1. Thermodynamics of Chemical Reactions

Some reactions of the scheme in Figure 18 are endothermic, in particular the gasification reactions of char with steam or carbon dioxide, which are significant in most gasification processes. (For heat effects of individual reactions, see Chap. 1)

The resulting heat requirement is met either by reactions with oxygen (in autothermic processes) or by an external heat source (allothermic process). Minimization of overall heat requirements has been one incentive among others for improving process efficiencies and economics.

For example, the idea of applying reaction conditions that favor the overall reaction

$$2\,C + 2\,H_2O \rightarrow CH_4 + CO_2$$

which is nearly thermoneutral, has affected gasification process development efforts during the times when production of CH_4 from coal appeared attractive.

In some of the chemical reactions of Figure 18, conversion is limited by equilibrium constraints under typical gasification conditions (temperature, pressure). Most significant in this respect are the reactions of char with steam, carbon dioxide, and hydrogen. Equilibrium constants for these and other reactions, as well as the effect of temperature, are presented in Chapter 1.

Thermodynamic analysis may aid in examining the limits for conversion and product gas composition as affected by such process variables as temperature, pressure, and stoichiometry. For example, the effect of temperature and pressure on equilibrium gas composition for individual char – gas reactions with steam, carbon dioxide and hydrogen is shown in Figure 19. The curves reflect two general equilibrium principles: (1) higher temperature favors products of endothermic reactions and (2) higher pressure shifts the equilibrium in the direction of lower amounts of gaseous components. Some past incentives of process development were based on thermodynamic analyses of gasification. For example, to produce methane-rich gases (substitute natural gas, SNG), high pressure and low temperature are advantageous under equilibrium

Figure 18. Main chemical reactions during gasification of solid carbonaceous materials

aspects. As a consequence, research and development efforts were directed toward applying higher pressure and enhancing feedstock reactivity (e.g., via catalysis), thereby lowering gasification temperature.

Figure 19. Effect of temperature and pressure on equilibrium gas composition in the presence of solid carbon

However, only the limits of conversion and product gas composition can be identified by thermodynamic analysis. In real gasification systems, equilibrium is generally not reached because of kinetic constraints.

4.1.2. Kinetics

Pyrolysis Reactions. Among the chemical reactions that occur during gasification, pyrolysis is generally fast. This is illustrated in Figure 20, which presents first-order rate constants of some reactions shown in Figure 18. Underlying values for activation energies and preexponential factors are taken from various literature sources (Table 14). Formation of tar, methane, and hydrogen as volatile products from Montana lignite is presented as part of pyrolysis.

The rates of primary pyrolysis product formation can be described by

$$\frac{\mathrm{d}V_i}{\mathrm{d}\,t} = k_{0i}\exp\left(-E_{\mathrm{A}i}/RT\right)\left(V_i^* - V_i\right) \tag{14}$$

where V_i is the total amount of product evolved from reaction *i* until time *t*, and V_i * is the value of V_i at $t \to \infty$.

Kinetic parameters for pyrolysis product formation have been determined for various kinds of coal and experimental conditions. Extensive compilations of pyrolysis data and kinetic information drawn from them can be found in review papers [51, 62].

Char – Gas Reactions. Of the char – gas reactions, combustion is generally fastest, and gasification is generally faster with steam than with carbon dioxide and hydrogen.

Table 14. Examples of first-order rate constants for reactions occurring during gasification (for nomenclature, see text)

		k_0, s^{-1}	E_A, J/mol	V *, wt %, (maf) [b]	Reference
Pyrolysis product formation	tar	2.0×10^{17}	315 281	3.5 (+ 2.9)	[63] (lignite)
	CH_4	4.7×10^{14}	290 578	1.1 (+ 0.4)	[63] (lignite)
	H_2	1.6×10^{18}	371 806	0.6	[63] (lignite)
Char – gas reactions	$C-O_2$	1.8×10^{6} [a]	113 050		[64] (bituminous coal)
	$C-H_2O$	4.1×10^{2} [a]	146 545		[65] (subbituminous coal), [66]
	$C-CO_2$	2.5×10^{2} [a]	146 545		[65] (subbituminous coal), [66]
	$C-H_2$	8.4×10^{-4} [a]	67 201		[65] (subbituminous coal), [66]
Tar cracking	coal tar	1.2×10^{9}	164 968		[67] (bituminous coal)
		8.0×10^{12}	272 992		[67] (bituminous coal)

[a] For $(p_i - p_i^{eq}) = 1.013\times10^5$ Pa (see Eq. 15).
[b] maf = moisture and ash free.

Figure 20. Examples of first order rate constants for reactions during gasification (pyrolysis product formation: Montana lignite [63], tar cracking: bituminous coal [67], char – gas reactions: bituminous and subbituminous coal [66]
Pyrolysis product formation: a) Tar; b) H_2; c) CH_4;Char – gas reaction: e) $C-O_2$; f) $C-H_2O$; g) $C-CO_2$; h) $C-H_2$

Although detailed kinetics include noninteger reaction orders and inhibiting effects of reaction products, simple first-order rate laws can be used for estimating and modeling purposes:

$$\frac{dm_c}{dt} = -k_0 \exp\left(-E_A/RT\right) m_c \left(p_i - p_i^{eq}\right) \quad (15)$$

where p_i is the partial pressure and p_i^{eq} the equilibrium partial pressure of reactant i, and m_c is the mass of solid carbon in the char. Values of k_0 and E_A for char – gas reactions vary with the kind of solid feedstock, according to its reactivity. Values of gasification rate constants for chars derived from various feedstocks vary with up to eight orders of magnitude. High transient reactivities can be observed under rapid heating conditions, (i.e., when pyrolysis and gasification of the resulting char occur simultaneously). Kinetic parameter values for char – gas reactions in Table 14 are taken from a modeling study of coal gasification in moving-bed reactors.

A characteristic of gas – solid reactions is the existence of a regime of temperature and pressure in which mass transfer affects overall kinetics. Extra- and intraparticle mass-transfer resistance can be incorporated in Equation (15) as follows:

$$\frac{dm_c}{dt} = -k_{eff} m_c \left(p_i - p_i^{eq}\right) \quad (16)$$

$$k_{eff} = \frac{1}{\frac{1}{k_g} + \frac{1}{\eta k_r}} \quad (17)$$

where k_g is an extraparticle (film) mass-transfer coefficient; k_r, a first-order chemical reaction rate constant; and η, an effectiveness factor that includes resistance to pore diffusion. The theoretical background can be found in reaction engineering textbooks (e.g., [68]; → Fluidized-Bed Reactors).

The temperature dependence of Equation (17) in its general form is shown in Figure 21. Accordingly, the chemical reaction is rate-controlling at lower temperature because it has the highest activation energy and extraparticle diffusion is limiting at high temperature.

In between ranks the intraparticle mass-transfer regime. Because these regimes may all play a significant role in technical gasification their limits must be defined by means of kinetic reactor analysis. The effects of feedstock reactivity, particle size, gas flow rate, and total pressure are discussed in [52].

Figure 21. Temperature dependence of effective rate constant for gas – solid reactions with porous particles, schematic representation
A) Film-diffusion controlling (c_G gas concentration, δ film thickness)
B) Pore diffusion controlling
C) Chemical reaction rate controlling

Gas-Phase Reactions of Volatiles. Gas-phase reactions of volatile pyrolysis products include a variety of individual reactions. Among them are cracking, reforming, combustion of tarry species and hydrocarbons, dealkylation, dehydroxylation, and shift conversion of carbon monoxide.

The rates of these reactions depend, in a complex way, on the reactivity of the reacting species and on reaction conditions (partial pressures, temperature, catalytic effects).

Again, first-order laws are sufficient for estimating and modeling purposes:

$$\frac{\mathrm{d}\,c_i}{\mathrm{d}\,t} = -k_0 \exp\left(-E_A/RT\right) c_i \tag{18}$$

where c_i is the molar (or mass) concentration of species i in the gas phase.

Values of kinetic parameters for tar cracking given in Table 14 were determined with freshly formed tar from bituminous coal [67].

Equations (14) – (16) and (18) can be used for describing source or sink terms in the balance equations in reactor models (see Section 4.2.3).

4.2. Classification and General Characteristics of Gasification Processes

4.2.1. Criteria for Classification

Processes for gasification of solid carbonaceous materials may be classified in the following ways (the abbreviations given are used in subsequent tables that present information on individual gasification processes):

1) Method of contacting solid and gaseous reactants (type of gasification reactor)
   - moving fixed bed
   - fluidized bed
   - entrained flow
   - molten bath
2) Kind of solid feedstock
   - coal
   - wood – biomass
   - solid waste materials
   - petroleum-derived residues
3) Particle size of solid feedstock
   - fine
   - medium
   - coarse
4) Gasifying medium
   - air (air)
   - oxygen (ox)
   - steam (st)
   - steam – air (st/a)
   - steam – oxygen (st/ox)
   - hydrogen (hydr)
5) Method of supplying heat required by gasification reactions
   - internal heating
     - autothermic (I/A)
     - cyclic (I/C)
     - heat-carrying fluids or solids (I/HC)
   - external heating (E)

heat transferred through walls of reaction vessel or heat exchanger (allothermic)

6) Operating pressure
   atmospheric
   elevated
7) Condition of gasification residue to be removed
   dry ash in nonslagging operation
   slag in slagging operation
8) Application of product gas
   fuel gas (medium or low Btu) (FG)
   fuel gas for combined cycle power plant (FG/ IGCC)
   synthesis gas (SG)
   substitute natural gas (SNG)
   source of hydrogen (H_2)
   gas for direct reduction of iron (RG)
9) Developmental status
   commercially available process
   process in developmental stage
      bench scale
      pilot-plant scale
      demonstration scale

Obviously, these criteria are not independent, and others could be used instead. An example is a characteristic gasification temperature, which determines product gas yield and composition, utility consumption, and the approach for predicting product gas composition and process performance (see Section 4.2.3).

For the purpose of this chapter, processes are presented according to the method of bringing the reactants into contact. This appears to be the most appropriate way of identifying process principles and characteristics, and is the most widely applied and accepted practice. Figure 22 shows examples of reactor types that represent different methods of contacting reactants.

4.2.2. Criteria for Process Assessment

Besides economics and availability, efficiency and other process performance criteria characterize individual gasification processes and aid in their comparison and assessment. Some commonly used criteria for practical purposes are defined in the following material.

Efficiencies

$$\text{Cold gas efficiency} = \frac{\text{higher heating value product gas}}{\text{higher heating value solid feedstock}}$$

$$\text{Gasification efficiency} = \frac{\text{higher heating value} \left\{\begin{matrix}\text{product} + \\ \text{byproducts}\end{matrix}\right\} (+ \text{ recoverable product heat content})}{\text{higher heating value solid feedstock}}$$

(Lower heating values are often used instead of higher heating values.)

$$\text{Carbonconversion} = 1 - \frac{\text{carboningasificationresidue}}{\text{carboninsolidfeedstock}}$$

Specific Gasification Rates

- Gas production rate per unit volume of gasifier
- Gas production rate per unit cross section of gasifier

Specific Production and Consumption Figures

- Gas (or byproduct) production per unit mass of solid feedstock
- Utility consumption per unit mass of solid feedstock
- Utility consumption per unit volume of product gas

4.2.3. Mathematical Modeling of Gasification Reactors

Mathematical models have gained importance as practical tools for designing gasification reactors and improving their operation and control. The general aim is to predict and interpret gasifier performance features such as

Product gas yield and composition
Utility consumption figures
Efficiency
Response time to input changes

as affected by

1) Solid feedstock characteristics (e.g., proximate and ultimate analysis, reactivity), and
2) Design and operational parameters (e.g., gasifier size, pressure, composition of gasifying medium).

Figure 22. Types of gasification reactor representing different methods of contacting reactants and operating temperatures A) Moving bed (nonslagging, countercurrent); B) Fluidized bed; C) Entrained flow; D) Molten bath

The degree of detail and the complexity of mathematical models depend on the particular type of gasifier and the task to be addressed. Progress in computing and in efficient algorithms, as well as the interest in coal gasification, led to numerous modeling activities and higher sophistication of models during the 1970s and later.

For gasification reactors, the following types of models are most widely applied:

1) Blackbox models (empirical correlations),
2) Equilibrium models, and
3) Kinetic models.

Blackbox Models (Empirical Correlations). Experimental data form the basis for correlation of commercial-size gasifier performance with feedstock characteristics and operational parameters. Such correlations are of great practical importance for all types of gasification processes. They usually require little fundamental knowledge and mathematical effort. However, because they are not based on fundamental principles, their usefulness for inter- or extrapolation is limited.

Equilibrium Models. Equilibrium models are valuable for identifying limits of conversion and product yields and for predicting reactor outlet conditions. This description is approximate because chemical equilibrium is usually reached only after long reaction times. Reaction rates become slow when equilibrium is approached, leading to long residence times or large reactor volumes to attain equilibrium conversion. How well an equilibrium approach can describe reactor outlet conditions in a real system depends on the rates of chemical reactions, mass transfer, and convective flow of reactants.

Equilibrium models are well established for high-temperature gasification systems (entrained-flow and molten-bath reactors), where chemical reactions are sufficiently rapid to approach thermodynamic equilibrium (e.g., [69]).

In gasifiers where product gas composition results from reactions occurring at lower temperature (e.g., fluidized-bed or moving-bed reactors), a defined deviation from chemical equilibrium can be incorporated by means of corrective factors for equilibrium constants or temperature differences between actual and equilibrium values [70, 71]. However, these restricted equilibrium parameters generally cannot be correlated with feedstock properties and operating variables on a fundamental basis. Therefore, capabilities for extrapolation are limited.

Kinetic Models. Kinetic models offer the possibility of describing local conditions in a chemical reactor, thus representing the process that eventually leads to reactor outlet conditions. Mathematical representation consists of differential equations based on balance equations for individual compounds and energy, including rate expressions for chemical reactions (e.g., Eqs. 14 – 18) and transfer of mass and heat. Because kinetic models provide the most detailed description of gasification reactors, they require a large number of parameters (activation energies, Arrhenius factors, mass- and heat-transfer parameters, etc.). Some parameters depend on feedstock characteristics and can be determined experimentally only with difficulty. Typical results of kinetic models are temperature and component concentration profiles in axial and radial directions. Examples of kinetic models can be found for moving-bed [66, 72], fluidized-bed [73, 74], and entrained-flow gasifiers [75, 76].

4.3. Characterization of Solid Feedstocks for Gasification

An overview of the molar ratios of carbon: hydrogen: oxygen for solid feedstocks is presented in Figure 23. Table 15 lists typical analytical data and Table 16 gives an overview of characteristic properties of different solid biomass and waste materials. Some of the most important properties that characterize solid carbonaceous materials are discussed briefly in the following. The significance of these properties depends on the type of gasification process.

Moisture Content. Solid carbonaceous materials have moisture contents ranging from $<$ 5 % (petroleum-derived residues and anthracitic coals) up to about 50 % (lignitic coals, peat, and wood). *Moving-bed gasifiers* can accommodate the highest moisture content (ca. 35 %) because the feedstock is dried in the gasifier by

Table 15. Data from typical solid feedstocks for gasification

	Delayed coke	Anthracitic coal (Ruhr)	Bituminous coal (Pittsburgh)	Lignitic coal (North Dakota)	Wood (redwood)	Municipal solid waste

exiting product gas. *Entrained-flow* and *molten-bath gasifiers* generally require that the moisture content be adjusted by predrying to maintain free-flowing behavior during crushing, conveying, and charging to the gasifier. *Fluidized-bed processes* can cope with higher moisture content which, however, in any case leads to lower process efficiencies.

Figure 23. Molar ratios C–H–O of feedstocks for gasification

Ash Content. Ash is present in petroleum-derived residues and wood in very low amounts ($< 1\,\%$) and in coals from 1 to $> 50\,\%$. For gasification, ash should be at a minimum because of the following reasons. High ash content is detrimental to carbon conversion. It furthermore must be heated to the gasifier outlet temperature, which leads to heat losses. In addition, provision must be made for withdrawing ash from the system, which increases in complexity and cost with increasing operating pressure. An exception is the *dry ash moving-bed gasifier* which can cope with high ash content (up to ca. 50 %) and utilizes sensible heat in the exiting ash to preheat the gasifying medium.

Ash fusion behavior is significant because in some gasification processes the ash must remain solid for removal (moving-bed nonslagging and fluidized-bed processes), whereas in others it is removed as a liquid slag (moving-bed slagging, entrained-flow, and molten-bath processes). Fusion temperature, therefore, must be thoroughly taken into account in the design and operation of gasifiers. Ash composition must be considered when selecting materials of construction, particularly for slagging gasifiers. Ash can vary in character from acidic to basic and can contain elements such as iron, which may separate or require special handling. Also, in slagging operation addition of reagents such as fluxes may be desirable to improve flow characteristics of the slag or to adjust its chemical behavior.

Ash can be beneficial when particular constituents like potassium enhance the kinetics of gasification, tar cracking, or other reactions.

Volatile Matter. Volatile matter refers to gas, tar, oil, and phenolic compounds formed by pyrolysis reactions of the feedstock. The yield of these volatile products determines the remaining amount of char that must be gasified in (relatively slower) gas – solid reactions. Pyrolysis product distribution depends strongly on feedstock characteristics and, to some extent, on reaction conditions during pyrolysis (temperature, heating rate, pressure, ambient gas composition, particle size [51]).

Fixed Carbon. The residual char remaining after pyrolysis contains the fixed carbon that must be gasified in gas – solid reactions with steam, hydrogen, carbon dioxide, air, or oxygen. Because these gas – solid reactions are endothermic for most gasification processes, the specific heat requirement per unit mass of feedstock (which in autothermic processes means specific oxygen or air consumption) depends on the amount of fixed carbon in the feedstock. Of the different feedstocks presented in Table 15, wood and municipal solid waste have the lowest value of fixed carbon, whereas delayed coke, petroleum-derived residue from a high-severity coking process, and anthracitic coal have the highest values.

Caking Behavior. Caking and swelling occur with certain coals, a phenomenon related to pyrolysis reactions. Certain bituminous coals with a high content of volatile material become fluid, and the particles may adhere together and swell. Other coals with similar volatile matter content may retain the original shape, with individual pieces caking together weakly. Still other solid carbonaceous materials (e.g., lig-

nitic coals) can disintegrate during pyrolysis into small pieces. Accordingly, feedstocks are referred to as strongly or weakly caking or noncaking. Fluidized-bed processes tend to be sensitive to strongly caking coals, whereas entrained-flow, molten-bath and moving-bed processes (with sophisticated mechanical stirrer systems) can generally accept feedstocks with caking properties.

Reactivity. Solid carbonaceous materials and their residual char from pyrolysis exhibit major variations in their reactivity to steam, hydrogen, carbon dioxide, and oxygen. This can be attributed basically to three factors [77]:

1) Concentration of active sites (i.e., carbon atoms located at the edges of crystallites or building blocks);
2) Diffusional limitations on how rapidly reactive gas molecules can reach active sites; and
3) Presence of catalytic inorganic impurities.

In technical gasification processes, reactivity affects the temperature level at which the gasifier must be operated to ensure acceptable carbon conversion. As a consequence, specific heat requirements (i.e., oxygen or air consumption in autothermic processes) are related to feedstock reactivity, to an extent dependent on the particular type of process. For example, low reactivity in combination with low ash fusion temperature may be prohibitive for dry ash removal gasification processes (e.g., fluidized-bed processes). Highly reactive feedstocks are particularly suited for methane production because low operating temperatures favor the formation of methane according to chemical equilibrium.

Of the feedstocks in Tables 15 and 16, wood, biomass waste, and lignitic coal are the most reactive, whereas petroleum-derived residues and anthracitic coal have the lowest reactivity.

Particle-Size Distribution. The particle-size distribution of a given carbonaceous material depends on its origin and characteristics: (1) system of mining (for coals), (2) type of coking process (for petroleum-derived residues), (3) kind of cutting (for wood), (4) kind of pretreatment (for waste materials), (5) mechanical strength, and (6) method of preparation and transport. For example, strip-mined bituminous coal may contain up to 30 % fines (< 3 mm) whereas heavily mechanized deep-mined coal may have 40 % or more, and strip-mined lignite can reach 60 % [55].

In *moving-bed gasifiers*, relatively coarse feedstock particles (3 – 50 mm) are preferred. The acceptance of fines is limited. Developments have moved, however, toward acceptance of a greater proportion of fines, either as agglomerates or by direct injection of fines into the gasifier. *Fluidized-bed, entrained-flow*, and *molten-bath processes* generally require pretreatment steps such as drying, crushing, and grinding to achieve an optimum feedstock size distribution. Coal mining techniques that result in high fines production offer an advantage in this case, because they help reduce costs of the coal preparation plant necessary for fine coal processes. Where a grinding step is needed, feedstock grindability is an important property that affects the kind and cost of equipment.

4.4. Moving- or Fixed-Bed Processes

In moving-bed gasifiers (also called fixed-bed gasifiers), the gasifying medium passes through a bed of granular or lump fuel. Figure 22 A shows a *nonslagging, countercurrent version*, which exhibits excellent thermal efficiencies because outgoing ash heats the incoming gases and outgoing product gas heats the incoming solid feedstock. The long residence times of solid particles moving through the bed (typically 1 – 2 h), together with the temperature profile of the countercurrent system, allow high carbon conversion efficiencies.

Tables 17 and 18 contain information on selected moving-bed gasification processes and typical performance data with coal and petroleum-derived residues as feedstocks. Dry ash and slagging pressure gasifiers are shown as examples in Figures 24 and 25.

In countercurrent moving-bed gasifiers, the solid fuel descends through four not distinctly separate zones with varying temperatures (Fig. 22 A) and gas compositions, where the chemical reactions outlined in Figure 18 can occur.

Drying and Pyrolysis Zone. Raw feedstock comes in contact with hot product gases, and moisture is driven off. Subsequently, pyrolysis of the carbonaceous material occurs to yield gaseous products and char.

Table 17. Selection of moving-bed gasification processes [a]

Gasification Zone. Char from the pyrolysis zone comes in contact with hot combustion products and steam from the zone directly below. Char – gas reactions occur mainly with steam, carbon dioxide, and to a lesser extent, hydrogen, so that the overall reaction is endothermic.

Combustion Zone. The combustion zone supplies heat for the gasification zone directly above. The key reaction is that of carbon (in the remaining char from gasification) with oxygen to produce heat and carbon oxides. Here, the temperature rises to a maximum, which in nonslagging operation must be kept below the fusion point of the ash by supplying steam in excess of that required to gasify carbon. In slagging operation, the steam supplied together with oxygen only slightly exceeds that required to gasify carbon. This results in temperatures of 1500 – 2000 °C, at which the ash melts and drains off as a liquid slag.

Ash Zone. In dry ash removal gasifiers, the ash bed, located at the bottom, heats the incoming gasifying medium by direct heat exchange and acts as a distributor.

Lurgi Pressure Gasification Process. A widely used version of the moving-bed gasifier is the Lurgi dry ash pressure gasifier (Fig. 24), which has been used commercially since the 1930s. The main gasifier shell is surrounded by a water jacket in which process steam is pro-

duced. A coal lock hopper is mounted on top of the gasifier to feed the coal (typically 3 – 50-mm particles), and a motor-driven distributor is used to spread incoming coal evenly over the coal bed. A mechanical stirrer is included in some designs to allow the gasifier to handle caking coals. A motor-driven grate at the bottom of the gasifier is used to withdraw the ash formed, which drops

Figure 25. Schematic of British Gas – Lurgi slagging gasifier (syngas production from solid waste materials, based on [80])
a) Feed preparation (metal removal, drying, pelletizing); b) Gas purification and conditioning; c) Clean gas utilization (methanol synthesis, combined cycle power generation); d) Air separation

into the ash lock hopper. Steam and oxygen (or air) are introduced at the bottom of the gasifier and distributed through the coal bed via the rotating grate. The grate supports the coal bed and is continuously rotated to ensure constant, even withdrawal of ash. Raw product gas leaves from the top of the gasifier (typically at 400 – 600 °C) and flows through a scrubber – cooler where it is washed by circulating gas liquor. Further cooling, cleaning, and conditioning of the gas must be done according to the desired application.

In the *British Gas – Lurgi Slagging Gasifier*, a slagging version of the Lurgi gasifier, the ash melts as a eutectic with potentially added flux to form slag. The high temperature in the combustion zone is a result of low steam oxygen ratios in the gasifying medium. Molten slag is tapped discontinuously through a taphole into a quench vessel, where the slag granulates as it drips into the quench water. One application of this process is the production of synthesis gas from various waste materials, as shown in Figure 25.

Compared to the dry ash process, the slagging version has higher capacities per unit volume (see Fig. 32), has lower hydrogen carbon monoxide ratios, and produces less aqueous condensate, tar, phenols, and hydrocarbons. These can be recycled and destroyed by gasification.

For *gasification of wood*, most moving-bed processes apply the *cocurrent* (or *downdraft*) system in which product gas flows through a hot zone before leaving the gasifier (Fig. 26). The advantage of this system is the low tar content of the product gas, because most of the condensable pyrolysis products are cracked while passing through the combustion zone. A higher tar content in the product gas does not cause a problem when a gas turbine is situated close to the gasifier since tars are kept in the vapor phase. An example of a wood gasification process is given in Table 17. Moving-bed gasifiers for wood gasification are suited to small-scale application (generally less than 200 kg of wood per hour). Performance data for a moving-bed downdraft wood gasifier are given in Table 21.

Figure 26. Types of moving bed gasifier for wood gasification
A) Countercurrent updraft; B) Cocurrent downdraft

For gasification of municipal waste together with other waste materials, practical experience is available with pressurized moving-bed gasifiers and with the new Thermoselect process (see

Table 21). In the latter case, raw municipal waste is pyrolyzed before being gasified under slagging conditions. In the case of moving bed gasification, pretreatment of the waste feedstock is required (extrusion/pelletizing, see Figure 25). Slagging operation ensures vitrification of the residue containing the inorganic material in the feedstock.

Some *advantages of moving-bed gasifiers* are: (1) the technology is mature with many commercial designs available, including pressure operation; (2) the large fuel inventory provides safety, reliability, and stability; (3) the dry ash gasifier can cope with high ash content feedstocks; (4) the gasifier may be banked for long periods; (5) the carbon conversion efficiency is high; (6) the thermal efficiency is high because of countercurrent flow and thus the specific oxygen consumption is low (see Fig. 33); and (7) the capability for turndown is high.

Some *limitations* of moving-bed gasifiers include (1) internal moving parts with some mechanical complexity are employed; (2) gasifier capacity is limited by gas flow rates (see Fig. 32); (3) feedstock fines must be handled separately (e.g., via agglomeration); (4) the product gas contains tar, oil, phenols, and ammonia, which require separation and cleanup systems; and (5) excess steam for temperature control leads to thermal losses and requires special condensate treatment.

Besides the processes mentioned in Tables 17 and 18, other moving-bed processes exist, some of which are of historical interest only: BCURA, Chevron, Demag, Foster Wheeler, Gegas, Gas Integrale, Grand Forks, Kellogg, KGN [81], Kilngas [82], Leuna, Morgas, Otto, Pintsch, Riley – Morgan, Wilputte, Woodall Duckham for coal gasification [55, 58, 78], and various processes for wood gasification [85, 94].

4.5. Fluidized-Bed Processes

Fluidized beds for gasification of solids are characterized by linear velocities of gasifying medium sufficient to lift the solid particles. This requires smaller particle sizes than moving-bed processes, typically in the 0.1 – 5-mm range (Fig. 22 B). As a result of fluidization, the solid particles move about randomly so that mixing of solids within the bed approaches that of a perfectly mixed reactor. Therefore, the solids composition and the temperature of the bed are nearly uniform, bed temperature being chosen according to feedstock reactivity. The maximum bed temperature is limited by the ash softening and sticking behavior. The temperature of reactor exit gases is about the same as that of the bed; a heat recovery device is required for energy economy.

Tables 19, 20 and 21 contain information on selected fluidized-bed gasification processes and typical performance data with various feedstocks. The number of processes in these tables reflects the fact that fluidized beds have been favored in many recent process development projects, mainly because they combine some advantages of moving-bed (e.g., large fuel inventory) and entrained-flow (e.g., control of hydrocarbon formation) gasifiers. In addition to the processes listed, others combine fluidized beds with various contacting methods, such as dilute phase entrainment or moving bed. An example is the *Hygas gasification process*. In Tables 19 and 20 the DMT process is listed as an example for an allothermic process, with heat from an external source (e.g., from a nuclear reactor or from hot flue gas) introduced via heat exchange bundles in the fluidized bed. These data are included although presently there is little commercial interest in the process.

Fluidized beds with gas velocities far above the minimum fluidizing velocity (3 – 10 m/s), called *circulating* or *fast fluidized beds* [95], are also used for gasification. They operate at lower bed densities and can thus cope with caking coals without particle agglomeration or sticking.

Winkler Gasification Process. The Winkler gasifier, the first commercially applied fluidized-bed process, has been in service since the 1920s for producing fuel and synthesis gases from coal (Fig. 27). The coal feed inlet is located in the lower part of the gasifier. Variable-speed screws feed crushed coal (< 9 mm) into the gasifier. Steam and oxygen (or air) are fed through nozzles located at several levels in the fluidized bed which occupies only the lower third of the gasifier; the remainder serves as a disengaging zone. Secondary steam and oxygen injection occur above the bed level to gasify unconverted carbon leaving the bed, tars, and hydrocarbons. Heavier particles drop through the fluidized bed and pass into the ash discharge unit at the gasifier bottom,

whereas lighter particles are carried up through the bed with product gas. Coal residence time is 20 – 30 min, based on coal feed rate. Carbon conversion is limited by feedstock reactivity and continuous loss of carbon with the ash.

Figure 27. Schematic of Winkler gasifier
a) Coal screw; B) Ash screw

A modification of the atmospheric Winkler gasification process has been developed (high-temperature Winkler process, HTW): It operates at elevated pressure (up to 1.0 MPa) and slightly increased temperature, i.e., conditions that considerably improve process efficiency and gas quality with respect to the requirements of a synthesis gas.

Figure 28. Schematic of U-Gas gasifier

U-Gas Gasification Process. A pressurized version of a fluidized-bed gasifier with controlled ash agglomeration is shown in Figure 28. The U-gas gasifier is a vertical cylinder with two cyclones for returning elutriated fines to the bed. A sloping grid at the bottom serves as the air and steam distributor and the agglomerated ash outlet. Noncaking coals can be fed directly to the gasifier from the crusher (particle size < 6 mm). Caking coals may require pretreatment by con-

tact with air in a second fluidized bed operating at gasifier pressure and 370 – 430 °C. Here, an oxidized outer layer forms on the coal particles and prevents agglomeration and possible blockage in the gasifier.

Coal is gasified with a mixture of air (or oxygen) and steam in a single-stage fluidized bed. Residence time of the particles is ca. 45 – 60 min. The fluidizing velocity is about 1 m/s. The key to gasifier operation is the agglomeration and separation of low-carbon ash from the bed. This is accomplished by keeping the temperature near the gasifying medium inlet close to the softening point of the ash particles. Thus, ash particles preferentially stick together, and the agglomerates grow until they are heavy enough to move downward and fall out of the fluidized bed.

The fluidized-bed system is particularly attractive for gasification of wood and other biomass because it allows greater feedstock flexibility (e.g., with respect to particle size) and easier scaleup than moving-bed gasifiers. There-

fore, several fluidized-bed concepts have been proposed and developed; a selection is presented in Table 21. As an example, Figure 29 shows a flow diagram for fuel gas production from biomass and waste feedstocks in a circulating fluidized-bed reactor integrated in a cement production plant. The feed material is fed to the lower part of the gasifier via a screw feeder. Air as gasifying agent is injected at the bottom. Because of excellent heat-transfer conditions, the temperature is uniform throughout the reactor and is high enough to convert the tarry and oxygenated pyrolysis products. Typical plant capacities for fluidized-bed wood and waste gasifiers are in the range of several tons per hour. The product gas is particularly suitable as feedstock for boilers, lime kilns, gas engines, and gas turbines.

Advantages of fluidized-bed gasifiers are: (1) commercial designs are available; (2) the technology is less complex than that of moving beds and does not involve moving parts; (3) the large fuel inventory provides safety, reliability, and stability; (4) a variety of particle sizes can be handled; (5) the amount of tar and phenols is low; (6) gas composition is steady due to uniform conditions in the bed; and (7) moderate gasification temperatures can be used.

Limitations of fluidized bed-gasifiers include the following: (1) capacity flexibility is limited by entrainment at high gas velocities; (2) the inventory of solid carbon is lowered

Figure 29. Flow diagram of a circulating fluid bed process for the production of fuel gas from biomass and waste feedstocks, integrated in a cement production plant, based on [103].

by the high content of inert material in the bed; (3) caking coal may require pretreatment; (4) conflicting temperature requirements exist for low-reactivity feedstocks with low-softening point ash; (5) inevitable loss of carbon in ash occurs due to uniform solids composition of the bed; (6) the turndown range is limited by the gas velocity required to maintain fluidization.

Besides the processes mentioned in Tables 19 20 21, other fluidized-bed processes are BASF – Flesch – Demag, Battelle – Union Carbide, Hydrogasification, *BCR*, CGT, CO_2-*Acceptor*, Electrofluidic process, Exxon catalytic process, Hydrane, Hydrogasification (HKV), Hygas, KRW, Synthane, Tosco, University of Wyoming, West Virginia University, Winkler – Flesch for coal or petroleum coke [55, 58, 117, 119], IGT's RENUGAS and various other processes for wood and waste gasification [54, 94, 118].

4.6. Entrained-Flow Processes

In entrained-flow gasifiers, solid particles are carried or entrained by the reacting gases. Thus, solids and gases move in the same direction with approximately the same velocity. To achieve this, the particles must be smaller than in other systems (typically 70 % $<$ 0.1 mm). This, together with high temperature (see Fig. 22 C), allows gasification rates high enough to ensure acceptable carbon conversion during the short solids residence time in the gasifier (a few seconds).

The reactants (e.g., coal, oxygen, and steam) are typically introduced into the gasifier at high velocity through one or more burners or nozzles. The burners can be oriented in many different ways, for instance, tangentially, radially opposed, and axially. Gasifier performance is affected to a large degree by the flow characteristics and mixing efficiency of the burners. The solid feedstock is either injected in the form of a water slurry or as dry particles.

Flame temperatures at the burner outlets can be as high as 2000 °C. This results in extremely rapid conversion of feedstock particles and destruction of virtually all higher hydrocarbons. Outside the immediate flame region, heat losses, further mixing with steam, and endothermic reactions combine to lower the gas-phase temperature. Because of the high reaction temperature, oxygen consumption is usually greater than for other gasification systems (see Fig. 33). A significant portion of the feedstock ash melts because of the high reaction temperature and is removed from the reaction zone as liquid slag.

Tables 22 and 23 contain information on selected entrained-flow gasification processes and typical performance data with coal or petroleum-derived residues as feedstock. Figures 30 and 31

show, as examples, a Koppers – Totzek gasifier and a scheme of the Texaco coal gasification process with gas cooler mode.

Figure 30. Schematic of Koppers – Totzek gasifier
a) Gasifier; b) Waste heat boiler; c) Slag quench tank

Koppers – Totzek Gasification Process. The two-headed Koppers – Totzek gasifier (Fig. 30) is horizontal and ellipsoidal in shape, with two heads mounted on the ends. A waste-heat boiler is mounted on top to recover heat from the hot effluent gases. The usual waste-heat boiler system, which produces high-pressure steam as a byproduct of the process, is a radiant surface boiler followed by a fire tube boiler. The gasifier shell is protected from the high gasification temperatures by a castable refractory lining. Coal is dried to 2 – 8 % moisture content (depending on coal rank) and simultaneously pulverized to 70 – 90 % below 80 µm. A variable-speed screw feeder feeds the pulverized coal into a mixing nozzle, where a premixed stream of oxygen and steam is introduced. Steam and oxygen entrain the pulverized coal, and the coal – steam – oxygen mixture is injected into the gasifier burners at injection speeds above the speed of flame propagation to prevent flashback. Two adjacent burners on each head improve turbulence behavior and provide a safety feature to ensure continuous ignition if one burner is temporarily blocked. Coal particles are gasified in approximately 1 s or less, producing a temperature in the flame zone of ca. 1900 °C. Heat losses and endothermic reactions cool the gas mixture to ca. 1300 °C. Ash in the coal is liquefied because the gasifier temperature is maintained above the ash fusion temperature. Most of the ash flows down the gasifier walls as molten slag and drains into a slag quench tank. Part of the ash leaves the gasifier as fine slag particles entrained in the exit gas. Pressurized modifications of the Koppers – Totzek process are the Prenflo and the Shell gasification processes (the latter jointly developed by Shell and Koppers), both using dry solid particles as feed.

TTexaco Gasification Process. The exaco coal gasification process (based on experience with oil gasification; see Section 3.2.2) uses a pressurized version of an entrained-flow reactor and a slurry system (Fig. 31). The gasifier is a vertical, cylindrical vessel with a refractory-lined upper portion where solid feedstock reacts with steam and oxygen. Hot product gas is cooled upon leaving the gasifier, either by direct quenching with water, resulting in internal steam production, or by indirect cooling in gas coolers with external high-pressure steam generation. The mode of operation is determined by the method of downstream processing and by the end use of the product gas. The quench mode is generally selected for the production of hydrogen or ammonia; carbon monoxide in the raw product gas reacts with steam in a carbon monoxide shift step to produce additional hydrogen. The gas cooler mode of operation is selected for applications that do not require carbon monoxide conversion (e.g., syngas for oxo synthesis or clean fuel for power generation). The solid gasifier feed is processed through two stages of dry grinding (the second under inert atmosphere) and pneumatically conveyed to slurry mix tanks where it is mixed with water to form a pumpable slurry (slurry solids loading 50 – 70 %). The slurry is fed continuously to the top of the gasifier by a positive displacement pump.

Advantages of Entrained-Flow Gasifiers. Among the advantages of entrained-flow gasification processes are: (1) commercial designs are available; (2) the gasifier has no moving parts and a simpler geometry than a fluidized bed;

(3) the gasifier has the highest capacity per unit volume (see Fig. 32); (4) any type of coal may be used without pretreatment; (5) no fines are rejected; (6) the product gas is free of tar and phenols (see Fig. 33); and (6) the slagged ash produced is inert and has a low carbon content.

Limitations of entrained-flow gasifiers include: (1) combustor nozzles and heat recovery in the presence of molten slag are critical design areas; (2) a small solids inventory requires advanced control techniques to ensure safe, reliable operation; (3) pulverizing and drying of surface moisture are required; and (4) the high gasification temperature causes thermal losses, necessitates higher quality construction materials, and leads to increased oxygen consumption (see Fig. 33).

Besides the processes mentioned in Tables 22 and 23, other entrained-flow processes are Babcock Wilcox, BiGas, Combustion Engineering, Foster Wheeler, GSP, and ORC for coal or petroleum coke gasification [55, 131].

4.7. Molten-Bath Processes

In molten-bath gasification processes, solid feedstock and gasifying agents are injected into

a hot liquid bath of molten slag, metal, or salt (Fig. 22 D). The high temperature normally required to keep the bath molten promotes high reaction rates, which are often enhanced by catalytic properties of the melt. The material employed for the melt largely determines the characteristics of each particular process. Slag acts mainly as a heat-transfer medium but can sometimes have a catalytic effect. Iron is used as a bath material because of its strong affinity for sulfur, its high solubility of carbon in molten iron, and because any iron oxide present in the melt will donate oxygen. Molten salts, which are generally less corrosive and have lower melting points than molten metals, may strongly catalyze the basic char – steam reaction, permitting prac-

tically complete gasification of some feedstocks at relatively low temperature.

As an example, the Molten Iron Puregas (MIP) Gasification Process uses an iron inventory of 20 t for a coal throughput of 10 t/h. The reactor is designed for gasification pressure up to 0.3 MPa and is brick lined. It contains liquid iron into which the feed coal is injected via an inert carrier gas, as well as facilities for feeding oxygen and other media that may be required such as lime for adjusting the basicity of the slag and steam for cooling the iron. Slag floating on the surface of the iron bath is discharged continuously and subjected to secondary treatment. Product gas leaves the reactor at ca. 1400 – 1500 °C and passes through a waste-heat recovery system followed by a dust removal system. Pilot-plant design enables optimum location of feeding points, either at the top (top blowing) or at the bottom (bottom blowing) of the reactor, to be investigated. This process draws on experience available from steelmaking technology.

Advantages of molten-bath gasifiers Among the advantages of molten-bath gasifiers are (1) the large fuel or heat inventory provides safety, reliability, and stability; (2) the high-temperature bath ensures safe ignition; (3) any grade of coal in a wide size range can be utilized (i.e., crushed run-of-mine coal); (4) no pretreatment or pulverization is required for gasifier operation; and (5) product gas contains no sulfur (retained in molten bath) and no tar or phenols at high temperature.

Limitations of molten-bath gasifiers include the following: (1) cleanup of molten media (if required) is complicated; (2) capacity flexibility is limited by melt entrainment in the product gas at high flow rates; (3) ash is removed as liquid slag, leading to loss of sensible heat; (4) the catalyst (if required) must be separated from ash for recycle, and make-up catalyst must be added; (5) the melt may be highly corrosive to refractory at the gasifier temperature; and (6) bottom blowing gasifiers require sophisticated cooling systems for the tuyeres.

Process variations include besides the Molten Iron Puregas Process (MIP) other processes for coal or petroleum gasification: Rummel [61], Rockgas Molten Salt [132, 133], Saarberg/Otto [78], Atgas, Kellogg, Klöckner, Sun [55, 134].

4.8. Underground Coal Gasification

[135 – 138]

The purpose of coal gasification in situ is to recover the energy or chemical values of the coal without mining. Gaseous products may be utilized for electric power generation, manufacture of organic chemicals, and synthesis of liquid or gaseous fuels. Advantages of in situ coal gasification are the elimination of underground mining operations and, possibly, the utilization of coal in beds that cannot be mined profitably. Included among past attempts are projects in Europe, the United States, and the Soviet Union. Although details vary from project to project, mixtures of oxygen and steam (or air and steam) must always be admitted into a hot zone in the coal seam for gasification to occur, and raw product gas must be withdrawn from the coal seam for surface processing to make the gas environmentally and technically acceptable. The main difficulties in underground coal gasification are creating and maintaining adequate permeability, maintaining and controlling the reaction zone, minimizing the detrimental effects of fissuring and channeling, and maintaining steady product

Figure 33. Characteristic temperatures of different gasification systems and correlation with selected performance data, based on published data
a) Phenols; b) NH_3; c) CH_4; d) O_2-consumption

gas composition and yield. Despite past projects, underground gasification of coal is not used widely at present and is not expected to play a significant role in the near future.

4.9. Environmental Aspects of Gasification

Gasification offers a practical means of utilizing coal, petroleum-derived residues, wood, or solid waste material while at the same time meeting stringent environmental control requirements. Although the type and severity of environmental control problem vary with gasification process, routine commercial operations have demonstrated successful cleanup of the most difficult streams.

Air Emissions. Among the sulfur compounds, reduced species (H_2S, COS, CS_2) predominate in gasifier raw gases and can be removed by a variety of processes (Chap. 5). Sulfur compound concentrations are higher in gasifier gases than in combustion gases, which facilitates their removal. For example, synthesis gas streams can be cleaned sufficiently for use in processes that require almost total removal of sulfur compounds because of the use of sulfur-sensitive catalysts. In addition, studies indicate that virtually complete control of sulfur in coal gasification increases product cost only moderately [53].

Particulates are routinely removed from synthesis gas produced by coal gasification to be fed to catalyst beds for chemical synthesis. In this case, particulates are removed to a far greater extent for catalyst protection than would be necessary to comply with environmental requirements. Of greater concern are emissions from feed lock hoppers or feed handling and storage systems; these, however, can be controlled if the equipment is designed properly.

Although nitrogen oxides are not formed to any appreciable extent in the reducing atmosphere of gasification, use of the product gas as fuel for combustion could pose an NO_x emission problem due to nitrogen compounds in the gas. However, well-cleaned product gas from gasification should yield an improvement over, for example, the direct firing of coal.

Water Effluents. Gasification processes in which raw gas leaves the gasifier at relatively

low temperature (moving bed) result in greater requirements for wastewater treating because of the tar and phenols produced, yet such wastewater can be purified adequately by conventional technology. For example, water effluent streams from Lurgi gasifiers have been well controlled on a large commercial scale at the Sasol II complex (→ Coal Liquefaction) in South Africa. Some gasification plants are designed for zero discharge in arid areas where discharges might seriously affect the quality of the receiving water.

Solid Wastes. All coal-consuming processes require the disposal of ash or slag resulting from the mineral content of coal. Some concern has been expressed that solid waste from gasification might be declared hazardous because of its leaching characteristics. However, leaching of gasification waste generally results in lower concentration of metals than leaching of power plant ash, which has not been classified as hazardous.

5. Gas Treating

Gas treating described in this chapter is often preceded by a separation stage for condensates obtained from cooling stages immediately following gas production (see Chap. 6). An overall gas treating sequence is described in Section 7.2.

Objectives. The method of gas treating is determined essentially by the following conditions:

1) origin (i.e., state and composition of the raw gas) and
2) utilization (i.e., specifications for the treated gas).

As described in previous chapters, the composition of raw gases differs considerably depending on the mode of production; this applies also to raw gas pressure and temperature (see Table 24).

Requirements for the treated gas are manifold. They are more or less stringent depending on whether the gas is to be used as a feedstock for synthesis or as fuel gas. Generally, no special requirements exist for fuel gas composition as long as the limits for calorific value and density are met (see Chap. 8). Purity is specified with a view to avoiding corrosion and deposits in the piping system or toxicity.

When syntheses follow downstream of gasification, the stoichiometry of the reaction requires a very specific composition, and the catalysts, which are generally sensitive, set very exacting standards for purity of the reactants. In addition, economic aspects must be considered concerning the inerts contained in the gas, which unnecessarily reduce the partial pressure of reactants and tend to concentrate in recycle processes so that a considerable amount of purge gas must be branched off.

Stoichiometric Conditions. Most syntheses of basic chemicals in very large quantities start from hydrogen and/or carbon monoxide, in conjunction with further reactants if necessary. The ratio of hydrogen to carbon monoxide offers a simple characterization (see Table 25).

Purity. Sulfur compounds, which are severe respiratory and catalyst poisons and may cause dangerous corrosion, are the subject of almost all purity specifications. The content of hydrogen sulfide (measured as sulfur) is generally limited to 2 mg/m^3 in long-distance pipeline systems. For syntheses, particularly those using sensitive copper catalysts, the permissible concentration is much lower: e.g., for the low-pressure methanol process, 0.1 ppm of total sulfur, measured as hydrogen sulfide.

In some syntheses, oxygen compounds are also undesirable: thus a content of

$$O_2+CO_2+2\,CO<20\ \text{ppm}$$

is usually required for ammonia synthesis (→ Ammonia). For reasons of corrosion, the oxygen content in gas grids is limited to 0.5 – 3 %. Nitrogen oxides are also undesirable because they may form unwanted or dangerous compounds with unsaturated hydrocarbons. This applies not only to syntheses but also to gas piping systems and cryogenic gas treatment processes (→ Cryogenic Technology; → Natural Gas). In view of the high process pressures, the nitrogen content of hydrogen used for hydrocracking is often limited to avoid formation of ammonia.

A number of other impurities, such as hydrogen cyanide, organic acids (e.g., formic acid),

or unsaturated and higher boiling hydrocarbons, are normally not included in purity specifications for synthesis processes because they are already undesirable in upstream process stages of synthesis gas production.

The total content of inerts (N_2, Ar, CH_4), which in most cases are not dangerous to synthesis but undesirable for economic reasons, must often be $< 2\,\%$.

To meet all these requirements, several process stages are necessary for gas purification or separation. They include catalytic processes (CO shift conversion, COS conversion, methanation; see Sections 5.1, 5.2, 5.3), as well as absorption, adsorption, and other fractionation processes (Sections 5.4, 5.5, 5.6, 5.7, 5.8).

5.1. Carbon Monoxide Shift Conversion

Processes for the manufacture of synthesis gas from hydrocarbon feedstocks produce mixtures of hydrogen, carbon dioxide, methane, and varying amounts of carbon monoxide. For the majority of industrial processes, this carbon monoxide content is higher than that required for synthesis. Exceptions include, for instance, the synthesis of oxo alcohols and of acetic acid from methanol and pure carbon monoxide.

The following are typical examples of commercial processes in which carbon monoxide in raw synthesis gas is partly or largely converted:

1) Adjustment to the desired hydrogen: carbon monoxide ratio in carbon monoxide-rich gases, which are formed, for instance, by partial oxidation (e.g., methanol synthesis);
2) Conversion of toxic carbon monoxide to carbon dioxide (e.g., town gas); and
3) Production of hydrogen from steam used for the carbon monoxide shift reaction (e.g., hydrogen production, ammonia synthesis).

5.1.1. Fundamentals

The water gas shift equilibrium among carbon monoxide, carbon dioxide, hydrogen, and steam

depends on temperature but is almost independent of pressure in the industrial range (elevated pressures up to 7.0 MPa).

Carbon monoxide shift conversion is an exothermic reaction:

$$CO + H_2O \rightleftharpoons H_2 + CO_2 \quad \Delta H_R^0 = -41.2\,\mathrm{kJ/mol}$$

The equilibrium constant is described by

$$K_p = \frac{p_{H_2} \cdot p_{CO_2}}{p_{CO} \cdot p_{H_2O}}$$

A number of models for the temperature dependency of the equilibrium constant and the heat of reaction appear in the literature. The temperature dependence of the equilibrium constant is shown in Chapter 1 (Fig. 1 and Table 3). Pressure influences activity and selectivity of the CO shift catalysts.

The various formulas, which are generally used for calculation of $K_p(T)$ and $\Delta H_R(T)$, give only slight differences for the temperature range of commercial processes. For the low-temperature range around 250 °C, the heat of reaction of shift conversion ΔH_R is ca. − 39.6 kJ/mol, it is about − 37.3 kJ/mol for the high-temperature range around 500 °C [139].

Above 950 – 1000 °C, the water gas equilibrium is established rapidly enough without a catalyst. In reforming processes using nickel-based catalysts, equilibrium is still attained at much lower temperatures. However, because nickel-based catalysts promote methanation of carbon oxides, they cannot be used for process steps in which only carbon monoxide shift conversion is desired.

The temperature ranges used in commercial carbon monoxide shift conversions are:

a) High-temperature shift (HTS): ca. 300 °C (start of run, SOR, with new catalyst) to 510 °C
b) Low-temperature shift (LTS): ca. 180 °C (SOR) to 270 °C
c) Raw gas shift (RGS): ca. 200 °C (SOR) to 500 °C.

Some catalyst manufacturers offer a so-called medium-temperature shift catalyst, which is normally a further stabilized LTS catalyst to operate at temperatures up to about 320 °C. Maximum temperature for *high-temperature shift* (HTS) is determined by the temperature resistance of the catalyst (sintering); minimum temperature, by the decrease in activity of this catalyst (large catalyst volumes are required). In *low-temperature shift* (LTS), the upper temperature limit is set by accelerated recrystallization of the copper catalyst (deactivation) above 270 °C; the lower limit by both the decline in catalyst activity and the need to keep the gas inlet temperature enough above the dew point of the gas – steam mixture to prevent condensation of water and subsequent damage to the catalyst. *Raw gas shift* (RGS) has a wide temperature range of application and the above explanations of temperature limits for HTS and LTS are similarly applicable for RGS.

In practice, at start of run equilibrium conversion can be reached whereas at end of run conditions typically an approach to equilibrium of about 40 °C is realized.

5.1.2. Catalysts

For carbon monoxide shift conversion in so-called clean gases (i.e., gases containing small quantities of impurities such as sulfur or condensable hydrocarbons) in the high-temperature range, iron – chromium oxide-based catalysts with trace additions of compounds containing sodium and potassium are used. At present HTS catalysts are often copper promoted. In the low-temperature range (LTS) copper – zinc – aluminum oxide-based catalysts with traces of potassium, etc. are commercially available [140, 141]. Some of these added elements act as promoters (enhancing activity, selectivity and providing self-guarding, i.e., chemically binding trace elements in the feed gas that would lead to catalyst poisoning) and some as stabilizers (increasing mechanical strength and active surface compositions at elevated temperatures and pressures) [142].

When new, catalysts often contain small amounts of sulfur. At present, the catalysts are sold mainly in tablet form and are stronger than the broken catalysts (iron oxide) formerly in use. In addition, their smooth surface and regular shape result in a smaller pressure drop through the catalyst bed.

High-temperature shift catalysts are supplied in the oxidized condition (i.e., iron is present as Fe_2O_3 and chromium as Cr_2O_3). Generally, the reduction necessary to activate the catalyst is not carried out before it is put into

the reactor, because the reduction process decreases the mechanical strength by up to 30 %. Therefore, the catalyst is reduced in situ with carbon monoxide- and hydrogen-laden gases, usually the clean gas itself. To control the reduction rate, the reducing gas is diluted with superheated steam or nitrogen (or both) to a mixture containing below 5 vol % ($CO + H_2$). During reduction the temperature profile of the catalyst bed has to be monitored carefully.

Iron oxide catalysts are resistant to appreciable amounts of impurities; even sulfur levels in the range of 10 to > 100 ppm (mL/m^3) can be tolerated at the cost of activity decrease. Rapid temperature and pressure changes caused, for example, by water coming into contact with the hotter catalyst (water evaporates in the pores) must be avoided. These maloperations lead to disintegration of the structure and, generally, to a rapid increase in pressure drop because of the accumulation of dust and pellet parts. All heating and cooling steps as well as pressure changes should be carried out gradually.

Low-Temperature Shift Catalysts. Stringent gas purity requirements must be met when using low-temperature shift catalysts because they are very susceptible to poisoning by sulfur or halogen compounds. Therefore, the gas must be cleaned to sulfur and chlorine contents of < 0.1 ppm (dry) upstream of LTS conversion. If this purity is not already met by the feed (e.g., from steam reforming of natural gas) or achieved by washing the raw gas (partial oxidation followed by Rectisol wash), a "guard bed" (usually a vessel filled with zinc oxide or LTS guard catalyst) must be installed upstream of the low-temperature conversion unit.

Raw Gas Shift Catalysts. Carbon monoxide shift conversion of gases containing appreciable amounts of sulfur or heavy hydrocarbons such as tar is known as raw gas shift conversion. For such gases catalysts consisting mainly of cobalt and molybdenum are used instead of the iron – chromium type. The activity of cobalt – molybdenum-based catalysts increases significantly between 4.0 and 8.0 MPa, whereas with HTS iron oxide catalysts, increasing the operating pressure above 4.0 MPa has practically no effect on the volume of catalyst required. RGS catalysts attain their full activity only in the sulfided condition. Therefore, they must be presulfided before installation or sulfided during start-up. A minimum content of sulfur compounds in the dry raw gas of ca. 100 to 1500 ppm (for gases from partial oxidation; the value depends on the steam: sulfur ratio) is required in normal operation to maintain catalyst activity. The minimum sulfur content in the feed gas also depends on other operating conditions (e.g., temperature). The sulfur content has no upper limit. The RGS offers the advantage of allowing sulfur and carbon dioxide removal to be accomplished in one step downstream the RGS unit [140].

The volume of catalyst required depends on the partial pressures of reacting components, the desired carbon monoxide content of the converted gas, and the reaction temperature. Normally, operating parameters are chosen to achieve space velocities of 1000 – 3000 m^3 (STP) of gas per cubic meter of catalyst per hour in the HTS range and 2000 – 5000 m^3 (STP) per cubic meter of catalyst per hour in the RGS and LTS range. If necessary, the process is divided into several steps with intermediate cooling or water quenching (see Section 5.1.5).

5.1.3. Clean Gas Shift Conversion

If the carbon monoxide-containing gas is substantially free of sulfur and heavy hydrocarbons, clean gas shift conversion is applied. In case the gas had to be desulfurized in an upstream purification stage, a cooler – saturator system is favorable. For naturally clean gases, (e.g., steam reformer outlet gas) only a simple HTS reactor is necessary.

Desulfurized feed gases derived from upstream partial oxidation and a physical or chemical washing unit usually enter the CO shift unit at a temperature between 20 and 120 °C. Thus, even if they are saturated with water vapor, the addition of a considerable quantity of high-pressure steam is required to effect satisfactory carbon monoxide shift conversion. For example, to lower the carbon monoxide content of a gas available at ca. 5.4 MPa and ambient temperature from 45 vol % (dry) to a residual ca. 3 vol % (dry) in two stages at a final reaction temperature of 380 °C, the addition of 1.18 kg of external HP-steam per cubic meter (STP) of gas is necessary. The cooler – saturator system, which generates steam in the saturator by using the reaction heat of the carbon monoxide shift con-

version, enables the quantity of external process steam to be lowered to 0.33 kg/m^3 (STP) of gas.

Cooler – Saturator System. Shift feed gas enters the saturator (a) at ambient temperature and rises through the tower packing while being sprayed with hot water (see Fig. 34). The gas becomes saturated with steam at ca. 225 °C. Heating of the gas – steam mixture is continued, more steam (0.33 kg/m^3 (STP) dry gas) is added, and the resulting mixture is fed to the first reaction zone (c). The temperature of the mixture rises due to the heat of reaction to about 500 °C. The first converter outlet CO concentration is about 6 to 8 vol % (dry). The hot gas is fed first to a gas – gas heat exchanger (b) to preheat the incoming mixture and then into a gas – water heat exchanger (e) to heat circulating water; by this means, it is cooled to ca. 350 – 360 °C. At this temperature, it enters the second reaction zone (d), where carbon monoxide is converted further to a residual content of ca. 3 vol % (dry), the gas being simultaneously heated to ca. 380 °C.

Figure 34. Flowsheet of a two-stage CO conversion plant with cooler – saturator system
a) Saturator; b) Gas – gas heat exchanger; c) Reactor 1; d) Reactor 2; e) Gas – water heat exchanger; f) Cooler; g) Waste Heat Recovery

Converted gas leaving the second reaction zone is cooled in a second gas – water heat exchanger (e). Then it enters the cooler (f) at ca. 230 °C. Here it is irrigated with colder water while it flows upward through a packed bed. By this means, most of the steam condenses, and water leaving the cooler is heated approximately to the dew point of the converted gas. The water leaves the cooler at ca. 210 °C. The cooler is often divided into two sections: the bottom section is fed directly with most of the water leaving the saturator; the top section is fed with a side stream that has been cooled to ca. 50 °C. The heat thus removed is used e.g., for boiler feedwater preheating, demineralized water preheating, etc. (g). By using such an arrangement, the gas can be cooled to about 60 °C.

Water from the cooler is heated to ca. 250 °C in the two gas – water heat exchangers (e) before entering the saturator (a), which it leaves at ca. 160 °C. Alternatively to the shown arrangement, in larger plants, the first gas – gas heat exchanger (b) can be installed inside reactor 1, to avoid the hot transfer piping.

Countercurrent Cooling Reactor. In smaller plants, a countercurrent cooling reactor (Fig. 35) is often used instead of two reaction steps in series. Whereas the reaction in a simple fixed-bed reactor proceeds adiabatically, which necessitates the two-stage mode of operation, a much more favorable temperature profile is achieved in the countercurrent cooling reactor.

Figure 35. Countercurrent cooling reactor
a) Gas entry into the cooling tubes; b) Surface of catalyst bed; c) Catalyst support grid; d) Manhole

The gas – steam mixture, which is not preheated to catalyst inlet temperature, enters the annular space between reactor shell and catalyst vessel, flows downward through this space, and enters the tubes of the catalyst vessel. While flowing through these tubes which are surrounded with catalyst, the mixture is heated

to ca. 380 °C. It then enters the catalyst bed from above. Due to the interaction between the temperature rise caused by the heat of reaction and the cooling effect of the gas mixture flowing through the cooling tubes, the temperature curve illustrated in Figure 36 develops. This type of reactor combines a high reaction rate at high temperature in the top section with a favorable equilibrium in the bottom section.

Figure 36. Temperature profile in countercurrent cooling reactor
a) Gas entry into cooling tubes; b) Gas entry into catalyst; c) Gas outlet (denotations a to c correspond with Fig. 35)

Carbon Monoxide Shift Conversion of Steam Reformer Outlet Gas. Shift conversion can be carried out more easily on product gases of a steam reformer for the following reasons: (1) the content of carbon monoxide is far lower (ca. 12 – 15 vol % in dry gas) compared to syngas produced by partial oxidation or coal gasification; that means generation of less reaction heat in CO conversion; (2) the required steam is already present in the steam reformer outlet gas, i.e., the gas has only to be cooled in the downstream waste-heat boiler to the inlet temperature of the shift converter (ca. 300 – 350 °C); (3) the gas is essentially free of catalyst poisons, as the reformer feed has to be purified before, because of the sensitivity of the reformer catalyst.

An example is the production of synthesis gas for ammonia manufacture from natural gas. After reforming in the primary and secondary reformer, and initial cooling in a waste-heat boiler, the reformed gas is, e.g., available at 2.9 MPa and 350 °C, and a steam content of 0.64 kg/m^3 (STP). It contains 10.5 vol % (dry) carbon dioxide, 11.7 vol % (dry) carbon monoxide, and 55.5 vol % (dry) hydrogen, the remainder being nitrogen and methane. After passing through the HTS conversion step, a carbon monoxide content of 2.2 vol % (dry) is obtained at 405 °C. The gas, which still contains 0.52 kg of steam per cubic meter (STP), is cooled to 220 °C and then fed to the LTS step. There the carbon monoxide content is decreased to ca. 0.3 vol % (dry), while the temperature increases to 232 °C.

Shift conversion of these gases is carried out either in one step in a HTS converter or in two steps, with intermediate cooling, in HTS and LTS converters. More recently quasi isothermal LTS reactors have been installed, reaching low CO contents at their outlet in a single step [143]. As a byproduct a significant amount of methanol is normally produced [141, 144].

5.1.4. Raw Gas Conversion

Raw gas conversion (sometimes also termed "sulfided CO shift") denotes the conversion of gases containing significant quantities of sulfur, soot, or condensable hydrocarbons. There are two principal industrial applications: (1) shift conversion of gases from heavy-oil gasification that have not been cooled and desulfurized but have only undergone hot quenching to add the required steam and remove soot; and (2) shift conversion of the carbon monoxide in gases from coal pressure gasification that contain not only sulfur but also saturated and unsaturated hydrocarbons, including tars. Cobalt – molybdenum based catalysts have proved particularly effective for converting both types of gas.

The carbon monoxide content (ca. 45 vol %, dry) of a gas from partial oxidation of heavy oil enters the carbon monoxide shift reactor at about 250 °C with a steam: dry gas volume ratio of ca. 2.4. The carbon monoxide content can be reduced to ca. 1.6 vol % (dry) over a cobalt – molybdenum based catalyst. Residual carbon monoxide contents of 0.5 – 1.0 vol % (dry) are attainable in a two-stage system even at lower steam: dry gas ratios. The sensible heat of the product gas is used to generate steam and to

preheat feedwater. Impurities in the gases for raw gas conversion, especially formic acid necessitate the use of mostly austenitic materials for streams with temperatures below the water dew point. Carrying out shift conversion on raw gases produced by coal pressure gasification is a good way of "detoxifying" town gas. The amount of steam present in the gas at 3.0 MPa and 180 °C, ca. 0.6 kg/m^3 (STP), is sufficient to reduce the carbon monoxide content from, e.g., 15.5 to ca. 5.0 vol % (dry). The cobalt – molybdenum based catalyst has a very useful side effect: unsaturated hydrocarbons in the gas are hydrogenated almost completely. Parallel to the CO shift conversion reaction COS is converted to H_2S; i.e., COS contents in the shifted gas reach low values close to equilibrium at catalyst outlet conditions.

5.1.5. General Comments on Reactor Arrangements

Apart from one-reactor applications several two-reactor systems are of commercial interest: two HTS (or RGS) reactors in series or one HTS followed by one LTS reactor, in each case with intermediate cooling. In the latter case a "guard bed" filled with zinc oxide is often installed between the HTS and LTS reactors to ensure that gas entering the LTS step is largely sulfur and halogen-free. Alternatively, the "guard bed" is filled with a smaller amount of LTS guard catalyst. Some HTS processes include water quenching between two reactor beds to cool the gas on the one hand and to add steam as a reactant on the other hand. In these concepts special caution has to be taken to avoid wetting of the catalyst.

5.1.6. Noncatalytic Quench Conversion

A less frequently used method of carbon monoxide shift conversion on raw gases is noncatalytic quench conversion. Here, advantage is taken of the fact that the water gas equilibrium is attained fairly rapidly above ca. 950 °C, even without catalysts. If, for example, oxo synthesis gas with a hydrogen: carbon monoxide volume ratio of 1.25 is to be produced from raw gas obtained by partial oxidation of asphalt and containing 48.9 vol % (dry) carbon monoxide and 43.9 vol % (dry) hydrogen, then 0.4 kg of cold water per kilogram of asphalt is sprayed into the hot (ca. 1570 °C) gas. As a result of cooling caused by the heating and evaporation of water and the associated carbon monoxide shift conversion (heat of reaction), the water gas equilibrium is attained at 1250 °C. The carbon monoxide content is then 38.3 vol % (dry) and the hydrogen content 47.8 vol % (dry), with a H_2: CO ratio as desired.

5.2. Carbonyl Sulfide Conversion

In all gasification processes based on sulfur-containing feedstocks, carbonyl sulfide is produced as well as hydrogen sulfide. For example, by partial oxidation of vacuum residues with a sulfur content of 3 wt %, a raw gas containing 0.71 vol % (dry) of hydrogen sulfide and 0.03 vol % (dry) of carbonyl sulfide is formed. Many modern gas washing processes remove carbonyl sulfide together with hydrogen sulfide. A selective carbonyl sulfide conversion (i.e., without parallel carbon monoxide conversion in a HTS or RGS converter, see Section 5.1) is limited to applications where there is no need for deep desulfurization (e.g., fuel gas for gas turbines).

Conversion of organic sulfur compounds in feedstocks for tubular reforming by hydrogenation over cobalt – molybdenum and nickel – molybdenum catalysts is described in Section 2.2.2.

Hydrogenation of carbonyl sulfide over iron oxide and cobalt – molybdenum based (see Section 5.1) catalysts occurs simultaneously with carbon monoxide shift conversion, and equilibrium in the form

$$H_2 + COS \rightleftharpoons H_2S + CO \quad \Delta H_R^0 = +10.9\,\mathrm{kJ/mol}$$

being established. In the CO shift conversion range at high temperatures of 350 – 500 °C, the equilibrium and the kinetics of this reaction lead to high COS conversion rates. When the gas mentioned above undergoes carbon monoxide shift conversion, the concentration of carbonyl sulfide in the product gas typically reaches values below 10 ppm (dry). (Table 3 lists a number of values of the equilibrium constant for this reaction in relation to temperature.)

A selective transformation of carbonyl sulfide to hydrogen sulfide is required in gases in which carbon monoxide shift conversion is not

desired. Catalysts have been developed for the selective conversion of carbonyl sulfide to hydrogen sulfide which are inactive for the water gas shift reaction. These catalysts promote hydrolysis of carbonyl sulfide according to

$$COS + H_2O \rightleftharpoons H_2S + CO_2 \quad \Delta H_R^0 = -30.2\,\mathrm{kJ/mol}$$

This reaction is catalyzed by chromium – aluminum oxide-based promoted catalysts, which work in a sulfided state. The commercially available catalysts are mainly not subject to poisoning by heavy metals and arsenic; but halogen compounds will lead to reduction of activity, selectivity, and lifetime. These catalysts are used at 150 – 320 °C; satisfactory equilibrium is attained at space velocities between 500 and 2000 m^3 (STP) per cubic meter of catalyst per hour [145]. As at lower temperatures the equilibrium conditions favor COS hydrolysis, less steam in the feed gas is needed to reach desired hydrolysis rates. (Values for equilibrium constants as a function of temperature are shown in Table 3.)

A typical reduction of the carbonyl sulfide content in gases from partial oxidation [assumed gas compounds (dry): 45 vol % H_2, 45 vol % CO, 5 vol % CO_2, 0.71 vol % H_2S, 300 ppm (mL/m^3) COS] to about 10 ppm is achievable by COS hydrolysis at 170 °C. A steam content of 0.086 kg per cubic meter (STP) of gas in this example corresponds to a saturation temperature of 150 °C at 5.0 MPa. In parallel to COS hydrolysis the contents of CS_2 and HCN are also significantly reduced. For some applications a separate bed for hydrogenation/hydrolysis of these compounds has to be installed additionally. For gases with low total sulfur content there are zinc oxide-based "absorption catalysts" commercially available, which can hydrolyze COS in the presence of steam (low concentrations) before H_2S is absorbed in the same bed.

5.3. Methanation and Methane Synthesis

5.3.1. Definitions and Applications

Methanation is generally defined as the catalytic reaction of hydrogen with carbon monoxide and/or carbon dioxide, forming methane and water, according to the description given in Section 5.3.2. Two main applications of methanation exist, which require very different technical solutions:

1) Methanation for the elimination of carbon oxides in hydrogen production: upstream of this final purification step the concentrations of harmful carbon oxides are rather low and the exothermic methanation reaction therefore causes only a moderate temperature increase, i.e., a single methanation step is sufficient (see Section 5.3.3).
2) Methanation for the production of SNG (Substitute Natural Gas): in this application, also called methane synthesis, hydrogen shall be converted to methane as completely as possible. Due to the strongly exothermic reaction and the high concentrations of all reactants measures have to be taken to limit temperature rises. As also the thermodynamics, i.e., the relevant equilibrium, ask for relatively low temperatures to yield high methane and correspondingly low hydrogen contents in the product, usually multiple-stage reaction systems will be required (see Sections 5.3.4 and 5.3.5).

Application (1) must be regarded as a well established technique with little incentive to improvements. It is widely used in hydrogen production, although nowadays pressure-swing adsorption (PSA) systems for hydrogen purification dominate the market. Catalytic systems may be damaged by too high temperatures due to breakthrough of carbon oxides as a result of sudden malfunctions of the upstream purification systems.

Application (2), the production of SNG, has lost commercial interest at present due to the increased availability of natural gas. The price of SNG cannot compete with that of natural gas. The development of new techniques for this kind of plants has therefore been terminated.

SNG production plants have demonstrated the reliability of processes for conversion of naphtha to SNG (Baltimore, USA) or coal to SNG (North Dakota, USA). Special local conditions — such as isolated distribution systems or missing storage capabilities — may be the reason for temporary implementation of SNG plants (for instance in West-Berlin before the German reunification, where only naphtha could

be stored at the time). A methanation system at low temperatures (with ruthenium-based catalysts instead of normally applied nickel catalysts) may find application in space technology [146]. In this projected application carbon dioxide from the breathing air is methanated in combination with a water electrolysis, thereby regaining oxygen for the biological cycle.

5.3.2. Principles of Methanation

The principle of catalytic synthetic production of methane from carbon monoxide and hydrogen was discovered in 1902 by Sabatier and Senderens. It is described by

$$CO + 3\,H_2 \rightleftharpoons CH_4 + H_2O$$

Carbon dioxide can also be converted to methane according to

$$CO_2 + 4\,H_2 \rightleftharpoons CH_4 + 2\,H_2O$$

Both reactions are linked by shift conversion, which is always observed simultaneously whenever active catalysts are used:

$$CO + H_2O \rightleftharpoons CO_2 + H_2$$

Many observations indicate that the transformation of carbon dioxide to methane is initiated by a reverse shift conversion reaction with hydrogen to yield carbon monoxide and steam. The carbon monoxide formed then reacts to yield methane:

$$\begin{array}{l} CO_2 + H_2 \rightleftharpoons CO + H_2O \\ CO + 3H_2 \rightleftharpoons CH_4 + H_2O \\ \hline CO_2 + 4H_2 \rightleftharpoons CH_4 + 2H_2O \end{array}$$

Both reactions for the formation of methane are strongly exothermic, as shown by Table 26. This table also indicates that low temperature and high pressure are required or favorable for high methane yield.

Kinetics. The mechanism and kinetics of methanation have been investigated, but these studies do not yield uniform results. The rate of conversion of carbon monoxide is often described formally by

$$r_{CO} = k_1 \cdot p_{CO}^m \cdot p_{H_2}^n$$

with $m = 0.7 - 1.0$ and $n = 0.3 - 0.5$.

Table 26. Equilibrium constants and heats of reaction (according to [147] for

1. $CO + 3\,H_2 \rightleftharpoons CH_4 + H_2O$, $K_1 = p_{CH_4} \cdot p_{H_2O}/p_{CO} \cdot p_{H_2}^3$
2. $CO_2 + 4\,H_2 \rightleftharpoons CH_4 + 2\,H_2O$, $K_2 = p_{CH_4} \cdot p_{H_2O}^2/p_{CO_2} \cdot p_{H_2}^4$

Temperature, K	Reaction 1		Reaction 2	
	K_1, bar^{-2}	ΔH_R, kJ/mol	K_2, bar^{-2}	ΔH_R, kJ/mol
400	0.409×10^{16}	−210.828	0.276×10^{13}	−170.172
500	0.115×10^{11}	−214.722	0.867×10^{8}	−174.862
600	0.198×10^{8}	−217.984	0.730×10^{5}	−179.070
700	0.372×10^{4}	−220.667	0.413×10^{3}	−182.771
800	0.321×10^{2}	−222.807	0.794×10^{1}	−185.953
900	0.766×10^{0}	−224.465	0.347×10^{0}	−188.658
1000	0.377×10^{-1}	−225.692	0.274×10^{-1}	−190.894
1100	0.319×10^{-2}	−226.609	0.338×10^{-2}	−192.816

In the purification of synthesis gas with a large excess of hydrogen, the reaction rate law is simplified to

$$r_{CO} = k_2 \cdot p_{CO}^m$$

Summaries and details can be found in the literature; see [148 – 150].

Kinetics must also be considered when investigating the possibility of undesirable side reactions. Kinetic effects have to be used to avoid the formation of carbon, because methanation usually begins in the temperature region where suitable thermodynamic conditions prevail for the Boudouard reaction to occur:

$$2\,CO \rightleftharpoons C + CO_2$$

(see Section 1.3). If thermodynamic equilibrium calculations indicate a possible buildup of carbon in the outlet region of the reactor, this undesirable side reaction cannot be excluded and may call for changes in process conditions. At the outlet zone of methanation reactors, attention must also be paid to the methane decomposition reaction

$$CH_4 \rightleftharpoons C + 2\,H_2$$

(see also Section 1.3.). However, a small residual hydrogen content and moderate temperature normally prevent this reverse reaction.

Catalysts. For the removal of carbon oxides from synthesis gases, catalysts with usually < 15 wt % nickel are used predominantly. Activated alumina, magnesium oxide and mixtures thereof are widely used as carrier materials. For the synthesis of methane from gases rich in carbon monoxide, catalysts with a high nickel content, similar to those used in reforming naphtha to a methane-rich gas, are usually employed. Catalyst poisons, must be eliminated carefully to the same level as in naphtha reforming (see Section 2.4.4) or even lower, because deactivation with time depends primarily on such impurities in the synthesis gas. Catalysts of the naphtha reforming type usually reach their limit of operation at about 500 °C. High-nickel catalysts with special aluminum oxide carriers and stabilization by zirconium oxide, which are capable of operating at 300 – 700 °C, are also available. The catalysts are used preferably in the form of cylindrical tablets measuring 5 × 5 or 8 × 8 mm.

Catalysts based on ruthenium have been tried repeatedly for methanation but have not found the broad application of nickel-based catalysts. Raney nickel coated reaction tube systems are also of little interest, because replacement of the spent catalyst appears complicated.

Metal Carbonyl Formation. Precaution must be taken with nickel-containing catalysts to prevent formation of highly poisonous *nickel carbonyl* [$Ni(CO)_4$] (TLV 0.1 ppm (mL/m^3) or 0.7 mg/m^3; see [151]).

In particular, low temperatures must be avoided because they favor the formation of carbonyls, as shown by Table 27. Generation of carbonyls is favored by nickel in reduced form, high total pressure, or high partial pressure of carbon monoxide [152]. The reaction is also promoted by sulfur, selenium, and tellurium. In practical operation of methanation plants, temperatures ≤ 200 °C at the nickel catalyst must be avoided, and procedures for start-up and shutdown must be adjusted accordingly. Formation of *iron carbonyl* also has to be prevented because of its toxicity and general corrosion problems, and because iron carbonyl decomposes and forms iron layers on the active surface of the catalyst as the temperature increases. Thus, carbon monoxide-laden synthesis gases must be heated in stainless steel heat exchangers. Many years of plant operation have shown that with adequate precautions, the formation of carbonyls can be suppressed successfully.

Table 27. Calculated nickel carbonyl content at equilibrium for various carbon monoxide concentrations as a function of temperature for a total pressure of 1.48 MPa (according to [152]), ppm (mL/m^3)

Temperature,	CO content, mol%				
°C	0.2	0.5	1.0	2.0	3.2
66	0.3	12	190	3 000	20 000
93	0	0.2	3	49	320
121	0	0	0.1	1.6	11
149	0	0	0	0.1	0.5
177	0	0	0	0	0.03
204	0	0	0	0	0

5.3.3. Methanation as a Step in Hydrogen Purification

Carbon oxides are often poisonous to *catalytic hydrogenation* processes. Their simultaneous elimination is possible by means of a methanation process step, which has been used widely since the 1950s and is nowadays competing with pressure-swing adsorption processes. Methanation remains the normal purification method for *ammonia synthesis gas* production, especially by secondary air reforming. Here, the nitrogen content prevents the use of other methods.

As shown in Figure 37, the inlet gas, containing ca. 0.5 – 0.8 mol % of carbon monoxide and the same amount of carbon dioxide, is heated by methanated gas in a heat exchanger (b). The final inlet temperature to the adiabatic reactor — typically 300 – 330 °C — may be achieved by a fired trim heater (c). In the adiabatic shaft reactor (a) filled with nickel catalyst, carbon monoxide and carbon dioxide are converted with hydrogen to methane and water vapor. Because the temperature increase in the reactor is ca. 70 K for each percent of carbon monoxide and about 55 K for each percent of carbon dioxide, the resulting outlet temperature can reach ca. 400 °C and the temperature gradient is then large enough to shut off the trim heater in continuous operation. Instead of the fired trim heater, other arrangements of heat exchangers in combination with the reforming plant are possible, as well as electrically operated start heaters. Purified hydrogen is then cooled to ambient temperature in the heat exchanger (b) and a final cooler (d), which also condenses most of the vapor formed.

Figure 37. Methanation as a purification step for hydrogen or synthesis gas
a) Reactor; b) Heat exchanger; c) Fired trim heater; d) Cooler

In synthesis gas purification of this type, the total content of carbon oxides is limited to ca. 2 vol %; otherwise, the temperature limits of the catalyst would be exceeded and the final content of methane in the hydrogen would be too high. Because of the loss of hydrogen by methanation, carbon oxides contents no greater than 0.8 % total are aimed at. Additionally, the residual content of carbon oxides is increased by higher outlet temperature and thus will not remain below the accepted tolerance of ca. 10 ppm (mL/m^3) for the sum of carbon monoxide and carbon dioxide.

5.3.4. Methanation of Rich Gas

Although methanation as a method of purifying synthesis gas yields only small absolute quantities of methane, methanation of rich gas and methane synthesis from gases high in carbon monoxide (e.g., produced by coal gasification) intentionally generate methane as product. Production of SNG by gasification of coal is being considered as a long-term replacement for gaseous hydrocarbons of natural origin when the latter are no longer available in sufficient quantity. In contrast, production of methane from rich gas (see Section 2.4.4) is restricted to specific areas where naphtha is abundant but no natural gas is available.

When SNG is produced from *naphtha*, the methane content of the rich gas is typically ca. 70 vol % (see Fig. 10, Section 2.4.4), whereas hydrogen amounts to ca. 7 % and carbon dioxide 25 %. Less than 0.5 % carbon monoxide is present, and unreacted steam from naphtha gasification amounts to ca. 1.30 mol of H_2O per mole of dry gas. Such a gas mixture can be enriched further by admitting it at an inlet temperature around 300 °C (i.e., after cooling downstream of gasification) to an adiabatic shaft reactor containing a nickel catalyst identical or similar to that used in naphtha reforming. Because the portion of unreacted steam is quite high and further steam is formed during the reaction, the degree of methane formation is limited in this so-called *wet methanation step*.

After cooling of the gas and condensation of steam, the methane content can be increased further by another methanation step (*dry methanation*), which may be up- or downstream of the required carbon dioxide removal. The *upstream* arrangement yields better methane quality, but the danger of carbon formation is higher due to the thermodynamic possibility of a reverse shift reaction and consequent formation of carbon according to the Boudouard reaction. Installation of the dry methanation step *downstream* of the carbon dioxide scrubbing system allows milder reaction conditions, but the carbon dioxide and hydrogen content of the product is increased slightly because of the need to provide excess carbon dioxide for the reaction of hydrogen.

A typical *analysis* of the final SNG is: methane 98.5 vol %, carbon dioxide 0.5 vol %, hydrogen 1.0 vol % and carbon monoxide < 0.1 vol %.

Figure 12, Section 2.4.4, shows a one-stage methanation system for rich gas installed upstream of the CO_2 removal system as part of the total plant concept for the production of SNG from naphtha.

5.3.5. Methane Synthesis from Gases with High Carbon Monoxide Content

Synthesis gases high in carbon monoxide are generated by various coal and oil gasification processes. These processes naturally result in different qualities of synthesis gas according to the feedstock used, the upgrading processes for

synthesis gas preparation, and the gasification process itself. Whereas high-temperature gasification processes yield high concentrations of carbon monoxide and little methane, interest in SNG production is concentrated on gasification processes that yield high methane content in the raw gas. This is possible, for instance, with Lurgi pressure gasification of coal, especially when gasification pressures of 8.0 – 10.0 MPa are applied, which has been successfully tested (see Section 4.4). Methanation processes with little methane in the raw gas suffer principally from (1) high exothermic heat release during methanation, (2) the very large quantities of synthesis gas that must be handled (four to five volumes of dry synthesis gas yield one volume of methane), and (3) the high proportion of steam formed during methane synthesis, which limits the directly achievable SNG quality in wet methanation steps.

Synthesis gases for methane synthesis are often classified by their stoichiometric number (SN), i.e., the ratio of the reactable hydrogen volume to the pro rata volume of carbon oxides:

$$\mathrm{SN} = \frac{\eta \cdot v_{\mathrm{H_2}}}{3v_{\mathrm{CO}} + 4v_{\mathrm{CO_2}}}$$

where η stands for an equivalent hydrogen consumption required for the hydrogenation of unsaturated and higher hydrocarbons in producing methane.

Because SNG specifications demand a hydrogen content of <10 vol %, a general classification may be SN $\leq$ 1.05. Because of restrictions in carbon dioxide content as well, the synthesis gas must meet the condition $0.98 < \mathrm{SN} < 1.03$ for stoichiometric methane synthesis, which is suitable for direct production of SNG. Such stoichiometric methane synthesis allows synthesis gas to be prepared by shift conversion and carbon dioxide removal. After methane synthesis, only compression to pipeline pressure (if the gasification pressure is not high enough) and drying (e.g., by a glycol system) are necessary. The quality of SNG varies slightly because fluctuations of the stoichiometric number are inevitably caused by variables and control functions of the gasification and upgrading processes.

In stoichiometric methane synthesis, little risk exists of carbon formation according to the Boudouard reaction, even in high-temperature methanation up to 700 °C. These problems become more serious at lower SN numbers. Lower stoichiometric numbers always require carbon dioxide removal as the final step before drying. The allowable load of carbon monoxide for the stoichiometric number of the synthesis gas must be determined experimentally for each gasification process. Individual optimization is necessary to attain lowest product costs, because shift conversion may be expensive if the necessary vapor is not provided with the raw gas. Among a vast variety of process configurations developed in the 1970s, the following are reportedly available for commercial operation. However, only the process with recycle has demonstrated reliability under the harsh conditions of commercial production, due to the lack of interest in SNG.

Besides the stoichiometric number, the highly exothermic reaction generally creates a problem for the design of methane synthesis plants: either the temperature increase must be limited by recycling of reacted gas or steam dilution, or special techniques such as isothermal reactors or fluidized beds, each with indirect cooling by evaporating water, must be used.

Recycle Methane Synthesis. Figure 38 shows a schematic of a methane synthesis plant with *hot recycle*. The type shown is designed as a two-stage recycle system with a final countercurrent-cooled reactor. These plants were originally designed for a recycle quantity such that 500 °C is not exceeded at the outlet of the adiabatic reactors. Current systems, optimized with regard to low secondary energy requirements, are available for maximum temperatures up to 650 °C. Inlet temperatures are ca. 300 °C, which is also the operating range of the recycle compressor. An advantage of the hot recycle is that water vapor formed during the methanation reaction is not condensed and, therefore, the stoichiometric number is not changed for the stages processing feed gas. Recycle systems show a high flexibility for accepting synthesis gases of very different natures [153, 154]. The waste-heat recovery system is normally designed to generate saturated steam up to 10.0 MPa, but superheated steam may also be withdrawn. Replacing the recycle compressor by a gas ejector reportedly produces positive results [155].

The higher the temperature selected for the first stage of methane synthesis, the more stages

Figure 38. Recycle methane synthesis
a) Recycle reactors; b) Steam drum; c) Countercurrent cooling reactor; d) Air-cooled cooler; e) Hot recycle compressor

must be applied to reach specification-grade SNG, for thermodynamic reasons. Therefore, with high-temperature methanation in the recycle stage(s), an intermediate step without feed gas addition at ca. 300 – 460 °C is required upstream of a final dry or wet methanation stage. The countercurrent cooling reactor in Figure 38, has a similar design to that described in Section 5.1.3 (Fig. 35). It allows product quality to be reached in one final wet step; otherwise, more stages are required to achieve the same analysis.

Steam Quenching Methane Synthesis. For synthesis gases with low stoichiometric numbers (low H_2: CO ratio), steam must always be added to prevent carbon formation. For optimum results, the required quantity of steam is mixed with a proportion of the feed gas in such a way that the temperature increase in the first methanation stage is kept within allowable limits and, after heat removal, a further portion of the feed gas is admitted to the first intermediate product gas stream as quenching stream. The quenching procedure after cooling is repeated until all the feed gas is consumed. Thus, a multistage concept results, depending on the inlet gas composition, as shown in Figure 39 for the RM process [156]. With the addition of steam, the equilibrium composition of any intermediate product gas is not favorable enough to enable direct production of specification-grade SNG in a wet methanation step. The removal of carbon dioxide, therefore, is followed by a final, dry methanation stage.

Fluidized-Bed Methanation. Intensive research and demonstration have been reported for the methanation of feed gases of unfavorable composition, with little or no addition of steam, in a cooled fluidized-bed reactor in one step without an additional cleanup reaction (Comflux process) [157]. The dangers of carbon formation, catalyst deactivation by high carbon monoxide partial pressure, and excessive catalyst consumption by the fluidized-bed process are said to have been overcome, and operation up to 6.0 MPa has been demonstrated successfully in the pilot plant.

Figure 39. Flow principle of multi stage quenching system – RM process

Isothermal Operation. By increasing the allowable temperatures for methanation catalysts, methane synthesis can be performed by a once-through method in quasi-isothermal reactors cooled by evaporating water, generating saturated steam. Under favorable conditions, such systems produce specification-grade SNG in only one catalytic step (IRMA process), but superheated steam can be produced only by combining isothermal and adiabatic reactors [158]. Any traces of sulfur compounds must be eliminated carefully, because poisoning of the catalyst will displace the temperature profile in the reactor and the reaction will not go to completion as the catalyst lifetime expires. Tests with isothermal reactors have been performed for methane synthesis within the ADAM – EVA systems for energy transport [159].

The ADAM – EVA Concept (Long-Distance Energy Transport System). Generally, methane synthesis is used to generate methane, the heat of reaction being an inevitable byproduct. However, a proposal by the Jülich Nuclear Research Center (KFA-Jülich, Germany) and the Rheinische Braunkohlenwerke (Cologne, Germany) uses the energy release of the methanation reaction as the essential product. The energy demand for the steam reforming of methane is provided by a nuclear high-temperature reactor; the resulting synthesis gas is then retransformed into methane a few hundred kilometers away, thereby providing thermal energy up to 650 °C. The methane is routed back to the nuclear system by a second pipeline to restart the cycle; thus, no fossil energy is used up.

$$CH_4 + H_2O \rightleftharpoons CO + 3\,H_2$$

Endothermic Exothermic

By the combination of power generation and energy distribution at a level of ca. 150 °C, an overall efficiency of about 60 % can be reached for such a chemical heat pipe system. A general flow diagram of this process is given in [160]. The use of high-temperature solar heating instead of nuclear power has been proposed for steam reforming of methane, however, solar ADAM – EVA systems may be restricted to a few favorable locations. Plans have been reported to provide energy that has been recovered and converted by high-temperature reforming in the Negev Desert to the industrial zones of Israel.

Studies have been made on the replacement of steam in the reforming step by carbon dioxide as oxidant [161]:

$$CH_4 + CO_2 \rightarrow 2\,CO + 2\,H_2$$

Although this reaction sequence significantly reduces the load in steam generation and can improve overall efficiency, transport of the thermodynamically necessary excess carbon dioxide in pipelines for both directions reduces this advantage. In addition, the danger of carbon formation in both reforming and methane synthesis at relatively high pressure must be examined carefully.

Other Synthesis Processes.

Methanation of Raw Gases. The dry product gas volume from methanation is only 20 – 35 % of the synthesis gas volume, depending on the gasification process and its yield of primary methane. Because nickel catalysts require complete removal of poisonous sulfur compounds,

relatively large amounts of gas must be handled in the upstream treating units. The Gas Research Institute in Chicago has proposed direct methanation of raw gases containing sulfur and carbon dioxide on special catalysts, to reduce gas volumes in acid gas removal. Savings in overall steam balance and in capital investment are claimed for such process routes. A final methanation step for cleanup in a sulfur-free atmosphere yields specification-grade SNG.

Liquid-Phase Methanation. A proposal by Chem Systems, Hackensack, N.J., is based on conventional gas preparation with methanation in the liquid phase [162]. Similar to processes employing fluidized-bed methanation or isothermal reactors, liquid-phase methanation appears to be able to handle high carbon monoxide concentrations and to yield high-quality methane in a single reactor. An inert liquid (aliphatic oil) containing dispersed catalyst is circulated and the feed gas is passed through this. The exothermic reaction heat is taken up by the liquid, mainly as sensible heat and partly by vaporization, resulting in excellent temperature control.

5.4. Absorption Processes

5.4.1. General

Principles. Processes that use a liquid solvent to remove one or more compounds from a gas stream are called absorption processes [140, 163 – 165] (→ Absorption).

The main purpose of absorption processes in gas production is the removal of acid gas components. They can also be used successfully to purify gases containing low concentrations of other components such as ammonia, higher hydrocarbons, water, cyanide, and organic sulfur compounds. Absorption processes are further applied to the withdrawal of gas constituents poisonous to catalysts or to the environment and also for the recovery of liquid gas or gasoline components from refinery gases.

In electric power generation from coal or liquid hydrocarbons by the combined power cycle process (see Section 7.3), absorption is used to selectively remove sulfur compounds and other impurities such as cyanide and mercury from the gas in order to meet gas turbine requirements and environmental regulations. So-called zero-emission IGCCs are discussed in view of CO2 emissions regulations and greenhouse gas abatement. Carbon of the feedstock is converted to carbon dioxide, which is removed in the absorption process and must be concentrated in a pure carbon dioxide stream for sequestration (see Fig. 59).

In the absorber, gas and liquid are brought into contact countercurrently. The solvent removes one or more components from the raw gas, more or less selectively. The absorber is usually equipped with trays or packing to provide a large gas – liquid contact area. The types most frequently used are valve and sieve trays. Bubble cap or tunnel trays are used only in special cases (a comprehensive treatment of trays and packings used in absorption is presented elsewhere; → Absorption).

The solvent laden with the absorbed components is withdrawn from the bottom of the absorber, routed to a regeneration system, where it is freed of absorbed gas components, and returned as lean solvent to the absorber. In most gas treating processes, absorption is reversible, and dissolved components are released chemically unchanged during regeneration. Liquid-phase oxidation processes for hydrogen sulfide removal differ in this respect (see Section 5.4.3).

The different absorption processes are characterized as *physical* or *chemical* depending on whether gas components are simply dissolved physically or are bound chemically to the solvent. Typical equilibrium lines for chemical and physical absorption are shown in Figure 40. Loading capacity c (kilomoles per ton or per cubic meter of solvent) is represented as a function of the partial pressure of the dissolved component. The loading in physical absorption, initially following Henry's law, is almost directly proportional to the partial pressure in the gas phase, which results in a nearly linear equilibrium line. The equilibrium line in chemical absorption is bowed sharply during saturation of the chemically active solvent component. After saturation of the chemical capacity of the solution, only weak physical absorption in the solvent's main component (usually water) is possible which results in a steep linear equilibrium curve.

At low partial pressure (e.g., p_2 in Fig. 40) the absorption capacity c_{ch} of the chemical solvent

is much higher than the absorption capacity c_{ph} of the physical solvent, whereas the physical solvent gives better results at high partial pressure, (e.g., p_1).

Figure 40. Gas – liquid equilibrium lines for (a) chemical and (b) physical absorption

The strong dependence of physical solubility on partial pressure can be utilized efficiently for solvent regeneration by means of simple flashing (i.e., pressure reduction). This improves the economy of operation considerably, particularly in case of bulk removal of impurities at high operating pressure.

If the dissolved components are chemically bound, less gas is released ($\Delta c_{\mathrm{ch}} < \Delta c_{\mathrm{ph}}$) when the solvent is depressurized. Thus, regeneration in chemical absorption processes is almost always accomplished by reboiling.

Fewer trays are generally required for chemical absorption than for physical absorption due to the acceleration of mass transfer by chemical reaction in the liquid phase and the low acid gas equilibrium pressure over the solvent at low loading.

Selection of Solvents. Selection of the appropriate solvent in a gas treating plant is most important because the solvent circulation rate determines equipment size and thus capital and operating costs. The following simplified rules are applicable, if linear dependence of the loading capacity on partial pressure across the entire concentration range in physical absorption and saturation of a chemical solvent above a certain partial pressure are assumed.

The solvent circulation rate required for *physical absorption* is largely independent of the concentration of the component to be removed but proportional to the total quantity G of crude gas and inversely proportional to the total pressure p and the absorption factor α_i. The minimum solvent circulation rate $L_{\min}$ required to remove component i completely can be estimated from the component balance around the absorber.

$$L_{\min} = \frac{G}{\alpha_i \cdot p}$$

The solvent circulation rate for *chemical absorption* is proportional to the quantity of the component to be removed and thus highly dependent on the concentration of this component in the gas, but practically independent of pressure. The maximum allowable concentration of the absorbed component in chemical solvents is often set by practical limits like increasing corrosion rate, increasing viscosity or tendency of foaming at higher loading.

In addition to these basic rules, the following points should be considered in selecting an absorption process.

Achievable Purity. High product gas purity can be obtained with many absorption processes, but only a few are suitable from an economic viewpoint. The minimum concentration of the component to be removed in the clean gas is mainly determined by the residual loading of that component in the lean solvent fed to the absorber top. Physical solvents can easily be regenerated to low residual loadings by pressure reduction and mild reboiling, whereas chemical solvents require high energy input for reboiling to achieve low loading.

Selectivity. The selectivity of a solvent is its tendency to absorb primarily one or a group of components from a gas mixture. Selectivity is often defined as the concentration ratio of component i to component j in the regenerator off-gas to the concentration ratio of component i to component j in the raw gas.

$$S = \frac{y_{\mathrm{i,off-gas}}}{y_{\mathrm{j,off-gas}}} \Big/ \frac{y_{\mathrm{i,raw-gas}}}{y_{\mathrm{j,raw-gas}}}$$

A high selectivity between the components to be removed and the product gas components is advantageous. High absorption rates of the

valuable product gas components reduce process economy and may affect treatment of the off-gas. If two or more components are to be removed from the raw gas and these components must be obtained separately, the solubility of the various components in the solvent should be different so that the selectivity is high.

Utilities. For chemical absorption, cheap low-pressure steam or waste heat with a sufficiently high temperature is generally required, whereas cheap electric power and cooling water at low temperature are an advantage for physical absorption.

Crude Gas Impurities. Impurities such as carbonyl sulfide, carbon disulfide, hydrogen cyanide, ammonia, mercaptans, thiophenes, phenols, heavy hydrocarbons, metal carbonyls, chlorides, and inorganic components such as mercury directly influence selection of both solvent and process [166]. Some trace compounds of the raw gas can react with the solvent or other absorbed compounds to form nonvolatile reaction products, which cannot be removed during regeneration. They accumulate in the solvent circuit and can lead to operational problems like plugging, foaming, corrosion and to solvent losses by degradation. Many commercial solvents are not capable of removing organic sulfur components and cyanide to the required low levels to meet emission regulations or downstream process requirements. Raw gases from coal gasification contain mercury which must be trapped. The alternative to the selection of a solvent which allows the removal of all these trace components in the absorption process step is the installation of a process chain consisting of COS hydrolysis and cyanide conversion reactors and adsorption guard beds.

Therefore trace components often determine the suitability of a solvent.

Other Solvent Properties. If the raw gas has to be dried or a low water dew point of the product gas has to be achieved, absorption processes using non-aqueous organic solvents are favorable. Aqueous chemical washes are preferable when upstream process stages produce water as a component of the treated gas mixture and this water is required in the product gas downstream. The laden and the lean solvent should be noncorrosive to avoid expensive materials of construction. High chemical and thermal stability reduce solvent losses due to degradation and avoid expensive solvent reclaiming. Toxicity affects solvent handling, storage, and safety equipment. The solvent should be easily available on the market.

The selection of an appropriate solvent can be supported by computer tools such as ABSORPERT (Ruhr-University Bochum [167]). This program contains heuristic rules, thermodynamic properties of a large number of solvents and a databank of industrial absorption processes. All the information is linked to provide an expert system for a systematic solvent selection and a basic process design based on the information of the feed stream and the desired separation.

Regeneration Methods. Absorption processes with solvent recovery consist, in principle, of absorption and regeneration (desorption) process steps. Several possible solvent regeneration methods are available; these are shown in Figure 41.

The simplest and cheapest method is flash regeneration (Fig. 41 A), in which the pressurized laden solvent, is depressurized in one or more stages. The residual content of dissolved components depends on the pressure in the last stage; therefore, this is often reduced to vacuum. Regeneration efficiency can be increased considerably by inert gas stripping (see Fig. 41 B). If the inert gas is completely free of the gas to be removed, the residual load of the solvent can be reduced as desired, provided the volume of stripping gas is large and the stripping rate is high enough. It is, however, unavoidable that the removed gas component is diluted by the inert gas. This may be desirable in some cases, whereas in others, further processing becomes economically prohibitive. Extremely high purity can be obtained without using inert gas if the impurities are removed in a hot regeneration stage (Fig. 41 C). This method makes use of the fact that, in general, the solubility of all gases decreases sharply with increasing temperature. The solvent is stripped by its own vapor, which is then condensed from the overhead gas and recycled as reflux. However, this method is rather costly in terms of capital investment (1) because it requires heat exchangers for the lean and laden solvent and a regeneration column with reboiler and condenser, and (2) because the utility demand for heating and cooling is rather high.

5.4.2. Processes for Carbon Dioxide and Sulfur Compound Absorption [168 – 171]

Numerous chemical and physical absorption processes are available for removing carbon dioxide and various sulfur compounds from raw gases. Hydrogen sulfide is the most widespread sulfur component and, like carbon dioxide, is an acidic compound. Other sulfur impurities that may be present in a raw gas are carbonyl sulfide, carbon disulfide, mercaptans, and thiophenes. A summary of chemical and physical absorption processes is given in Table 28.

Physical absorption processes are used predominantly to remove carbon dioxide and hydrogen sulfide from gases with high carbon dioxide partial pressure, especially converted gases produced in partial oxidation plants based on coal or residual oil. Here the partial pressure of carbon dioxide is above the level appropriate for economic application of chemical absorption systems.

Chemical absorption process (normal amine based) are used widely, especially for crude gas containing carbon dioxide and hydrogen sulfide at low partial pressure. As shown above, various amines are employed. The selection of amine is influenced by specific process conditions such as the presence of further impurities in the raw gas, which may cause solvent degradation, corrosion and foaming. Low coabsorption of valuable gas components in the aqueous amine solution is an advantage of all amine processes.

Table 28. Absorption processes for acid gas removal

Trade name	Solvent	Licensor
Chemical absorption with aqueous amine solutions		
MEA	1 – 3 N monoethanolamine	free process
DEA	2 – 4 N diethanolamine	Elf Aquitaine and others
DGA/ Econamine	4 – 6 N diglycolamine (2-(2-aminoethoxy)ethanol)	Fluor Daniel, Huntsman
DIPA	2 N diisopropanolamine	Shell and others
MDEA	2 – 5 N methyldiethanolamine	free process
ADIP	DIPA or MDEA	Shell
Amine Guard/ Ucarsol	formulated MDEA	UOP/Union Carbide
aMDEA	MDEA + activator for enhanced CO_2 absorption	BASF
Gas Spec	formulated MDEA	DOW Chemical
Flexsorb	hindered amine	Exxon
Chemical absorption with alkaline solutions (hot potassium carbonate)		
Benfield	K_2CO_3 + activator (DEA)	UOP
Catacarb	K_2CO_3 + catalyst	Eickmeyer
Giammarco-Vetrocoke	K_2CO_3 + activator (arsenic trioxide)	Giammarco
Vacasulf	K_2CO_3 + NaOH	Krupp Uhde
Physical absorption		
Rectisol	methanol	Linde/Lurgi
Selexol	polyethylene glycol dimethyl ether (DMPEG)	UOP
Purisol	*N*-methyl-2-pyrrolidone (NMP)	Lurgi
Morphysorb	*N*-formylmorpholine (NFM)	Krupp Uhde
Physical – chemical absorption		
Sulfinol D/M	sulfolane (tetrahydrothiophene oxide) + DIPA or MDEA	Shell
Amisol	methanol + MEA, DEA or DETA	Lurgi

Sulfur components like hydrogen sulfide, carbonyl sulfide, and mercaptans have a higher solubility in physical solvents than carbon diox-

ide. This facilitates production of a sufficiently hydrogen sulfide rich gas for the sulfur recovery process. Compared to aqueous amine solutions, selectivity with regard to valuable components is lower in organically based physical solvents, which leads to higher losses of these components.

Amine solutions do not show a selectivity of hydrogen sulfide over carbon dioxide at equilibrium. Therefore, very high sulfur purity can be obtained only if carbon dioxide is removed simultaneously to a very low level. However, the reaction rate of certain amines with hydrogen sulfide is much higher than with carbon dioxide. Hydrogen sulfide can therefore be selectively removed by utilizing this difference in reaction kinetics. In the absorber a large gas liquid interfacial area has to be provided for a fast hydrogen sulfide mass transfer to achieve the required low sulfide concentration in the purified gas. Simultaneously a short contact time between gas and liquid is required so that only a small portion of the absorbed carbon dioxide can react with the amine [172].

Figure 42. Equilibrium curves of CO_2 in various solvents a) H_2O (30 °C); b) *N*-methyl-2-pyrrollidone (40 °C); c) Methanol (− 15 °C); d) Methanol (− 30 °C); e) Hot potassium carbonate solution (110 °C); f) Sulfinol solution (50 °C); g) 2.5 M Diethanolamine solution (50 °C); h) 3 M Amisol DETA solution

In an attempt to combine the advantages of chemical and physical absorption, processes using chemical absorbents mixed with organic solvents have been developed. These processes, termed *physical – chemical absorption processes* or *mixed solvent processes*, are suitable both for absorbing carbon dioxide and hydrogen sulfide and for removing organic sulfur compounds, giving high end purities. A survey of the equilibrium behavior of carbon dioxide in common solvents is shown in Figure 42.

Initial selection of a gas purification process based on the partial pressure of the acid gas in the raw gas versus the product gas specification can be done with the aid of Figure 43.

Figure 43. Selection of appropriate gas purification process for simultaneous H_2S/COS and CO_2 removal

If the acid gas partial pressure in the raw gas is very low, *dry-bed adsorption processes* (e.g., solid beds of zinc oxide, iron oxide, activated carbon, or molecular sieves) or nonregenerable scavenger solutions are used for gas cleaning.

5.4.2.1. Physical Absorption Processes

Water was an industrially important solvent for carbon dioxide absorption, particularly in ammonia synthesis, until organic solvents were introduced. Organic solvents have a much higher solvent capacity than water, which improves process economy.

Organic solvents are especially suitable for treating converted raw gases obtained from partial oxidation of oil or coal. The carbon dioxide partial pressure in these gases can be as high as 2.5 MPa. At this high acid gas partial pressure the solvent capacity, i.e. solvent loading,

of organic solvents exceeds that of chemical absorbents considerably.

Rectisol Process. The Rectisol process, invented by Lurgi around 1950 and developed further together with Linde, is particularly suitable for the specific requirements of high-pressure synthesis gas production [173].This process achieves syngas quality with very low total sulfur content in the ppb range and removal of all impurities and bulk CO2 in one process step. More than 60 Rectisol units were reported to be operating worldwide in 2005 purifying more than 210×10^6 m^3/d (STP) of synthesis gas, which is equivalent to more than 75 % of the gas produced from coal, oil, and waste gasification.

Originally designed and applied in conjunction with Lurgi pressure gasification of coal, the Rectisol process is now also used successfully in oil-based synthesis gas plants and other coal gasification processes, as well as in special cases of natural gas treatment.

The Rectisol process uses cold methanol as solvent. The solubility of acid gas in methanol increases strongly with decreasing temperature whereas the solubility of the valuable light components is almost temperature independent. Temperatures as low as − 75 °C are therefore applied in order to minimize the required solvent circulation rate and the loss of valuable gas components. The low operation temperature also reduces solvent losses into the product streams by lowering the vapor pressure of methanol. Good mass and heat transfer are provided by methanol due to its low viscosity. Operating the process at low temperature does not necessarily require large refrigeration units. The major part of the cooling is done by internal heat exchange and by utilizing the temperature decrease by gas desorption and expansion. In Figure 44, the temperature dependence of the absorption coefficient λ, which is defined by $c = \lambda p$, is shown for various gases at 1 bar. The absorption coefficient is not entirely pressure-independent but rises above the value measured at 1 bar as the partial pressure of the gas approaches its saturation vapor pressure. The nonideal behavior of the gas phase at higher total pressure also must be considered to model the gas liquid equilibria correctly (→ Absorption).

Figure 44. Absorption coefficient λ of various gases in methanol at low pressure (1 bar)

Standard Rectisol Process. In gas production, the Rectisol process is used in two basic configurations: the nonselective standard process and the selective process configuration. All acid gas constituents are absorbed simultaneously in the standard Rectisol process. The basic flow diagram of the standard process with two absorption sections is shown in Figure 45. Flash-regenerated methanol, fed to the lower part of the absorber, largely removes hydrogen sulfide and carbon dioxide at bottom temperatures between − 10 to − 30 °C. The remaining hydrogen sulfide and carbon dioxide are removed from the gas to the required purity by heat-regenerated cold methanol in the absorber top section.

Under these process conditions, solvent loading is very high at the *bottom of the absorber*, which results in a low solvent rate. The heat of absorption raises the temperature of the solvent; the absorber bottom temperature may be as much as 50 °C higher than the solvent inlet temperature. During flash regeneration of the solvent, this heat of absorption is given off. and the solvent temperature drops accordingly. The applied low absorption temperatures are generated

Figure 45. Standard Rectisol process for simultaneous removal of H_2S and CO_2
a) Absorber; b) Flash tower; c) Hot regeneration; d) Condenser; e) Methanol – water column

in this desorption step and not by the refrigeration unit. This phenomenon is often referred to as the "autorefrigeration effect". In the *fine wash section* of the absorber, only the residual acid gases are removed. Therefore, little heat of absorption is released in the fine wash section and the temperatures remain low. Moreover, there is a smaller quantity of gas to be treated in the fine wash section. Therefore, solvent demand in the fine wash section is considerably lower than that in the main section of the absorber. This is desirable in view of the high investment and utility costs for hot regeneration.

In Fischer – Tropsch synthesis, SNG, and town gas plants, carbon dioxide must only be removed to a final content of 1 – 2 %. This value can even be reached in the main wash part with flash-regenerated methanol. The fine wash part then has to be designed only for removal of hydrogen sulfide and carbonyl sulfide, which results in a lower solvent rate, normally one-tenth of the total amount of solvent withdrawn from the bottom, due to the higher solubility of these components.

Downstream of hot regeneration, a methanol – water distillation column is used to separate water entering with the raw gas. To prevent icing in the cooling section of the raw gas, a small amount of methanol is injected upstream of the heat exchanger. The mixture of methanol and water is withdrawn and fed directly to the distillation column. A refrigeration unit is used to cover cold losses in the plant due to surge energy, incomplete heat exchange, unrecovered heat of absorption, and insulation losses. An ammonia absorption refrigeration unit can be advantageously applied if low temperature (130 – 200 °C) waste heat is available.

The standard Rectisol process combines all absorbed gases in a single acid gas stream. The sulfur compounds are thus diluted with the entire absorbed volume of carbon dioxide. (Referred to the raw gas specification in Table 24, only 0.9 vol % of hydrogen sulfide [example 2] and only 1.8 vol %, of hydrogen sulfide [example 4] in the off-gas are typical of the standard process with complete removal of carbon dioxide.) The off-gas with this low sulfur content is not suitable for sulfur recovery in a Claus process. Other sulfur recovery processes must be applied such as liquid-phase oxidation (see 5.4.3) or adsorption. The standard Rectisol process is therefore advantageously applied for gases from low-sulfur feedstock.

Selective Rectisol Process. Initially the selective Rectisol process was introduced to produce an off-gas rich in hydrogen sulfide which could be processed in a Claus plant for sulfur recovery. Pure carbon dioxide is produced as a second product with a total sulfur content in the low ppm range. This stream can be vented to atmosphere or utilized, for example in urea plants, which are often built in conjunction with ammonia plants, or recovered in food grade (see Section 6.3),or can be used for enhanced oil recov-

Figure 46. Selective Rectisol process for separate removal and recovery of H_2S and CO_2
a) H_2S absorption; b) CO_2 absorption; c) Flash regeneration; d) Stripper; e) Reabsorber; f) Hot regeneration

ery and sequestration. The solvent loops shown in Figure 45 are interchanged for that purpose (see Fig. 46). The raw gas is first desulfurized with a small amount of heat-regenerated methanol. The carbon dioxide coabsorption is low because of its low solubility and the presaturation of methanol in the carbon dioxide absorption column.

Most of the carbon dioxide and the remaining traces of sulfur compounds are removed in the downstream carbon dioxide scrubber in two stages, by using flash-regenerated methanol in the middle section and heat-regenerated methanol in the top section.

Depending on the requirements, carbon dioxide may be removed down to a few percent or even a few parts per million. Removal of both carbonyl and hydrogen sulfides as well as mercaptans to 0.1 ppm is ensured in all cases.

According to Figure 44, the selectivity between carbon dioxide and hydrogen sulfide for the raw gas indicated in column 4 of Table 24 is not sufficiently high to give an off-gas rich enough in hydrogen sulfide for the Claus process. Therefore, an additional concentration stage is required before the solvent passes to hot regeneration. In the bottom section of the reabsorber column (d in Fig. 46) carbon dioxide is stripped out of the laden solvent by simple pressure reduction or stripping with inert gas. In the top section (e) the small amount of hydrogen sulfide which is stripped together with the carbon dioxide in the bottom section is reabsorbed with methanol to yield a sulfur-free off-gas.

In the selective Rectisol process, much more solvent must be treated by hot regeneration than in the standard Rectisol process. Additional methanol is required in the reabsorber, and more methanol is necessary in the hydrogen sulfide absorber because the entire gas rate must be treated at higher temperature.

To avoid the extra load on the regeneration unit, the two Rectisol wash steps can be separated by removing the sulfur compounds upstream of carbon monoxide conversion, with carbon dioxide removal located downstream of the conversion unit. The solvent loops of both absorption steps are still combined. A classic application of this case is synthesis gas production by residual oil gasification.

As shown in Table 24, example 3, the ratio of hydrogen sulfide to carbon dioxide upstream of shift conversion is approximately ten times higher than downstream (example 4). Therefore, the natural selectivity of methanol is sufficient to produce a sulfur-rich off-gas suitable for sulfur recovery in a Claus process. In addition, the gas rate upstream of carbon monoxide conversion is only 70 % of the rate downstream; therefore, less solvent is required for desulfurization. This simplification of the gas treating unit, combined with the advantage of passing a sulfur-free gas to the carbon monoxide conversion unit and the possibility to apply low-temperature shift conversion for minimum residual carbon monoxide in the raw hydrogen, must be paid for by cooling the gas twice.

Because the selective Rectisol process is much more complex than the standard process, a decision must be made in each individual case as to which route gives the most economical solution in conjunction with the downstream plant and the sulfur recovery unit.

For Fischer – Tropsch synthesis and SNG plants based on coal with a low sulfur content (example 2 in Table 24; pure carbon dioxide is not required in either case), the standard Rectisol process has mostly been used, with the off-gas being treated in a special chemical system.

A two train Rectisol plant is shown in Figure 47. Part of the raw gas from a residual oil gasification is shifted and purified in the first train to produce pure hydrogen. The remaining raw gas is purified in the second train giving gas for oxo synthesis. The solvent of both trains is regenerated in a common hot regenerator column.

Applications [174, 175]. In view of (1) the high flexibility with regard to carbon dioxide, hydrogen sulfide, and carbonyl sulfide removal, as well as the removal of various trace compounds, (2) the high purity of the treated gas, and (3) the absence of corrosion at low temperature, the Rectisol process is used in the following cases:

Standard processes are used for raw and converted gas from coal gasification (in this case, combination with prewash systems for other impurities is also possible).

Selective processes with two *absorption steps immediately following* are used for raw and converted gas from coal or oil gasification plants.

Figure 47. Two train selective Rectisol plant downstream of residual oil gasification producing 40 000 m^3/h (STP) gas for oxo synthesis from unshifted gas and 30 000 m^3/h (STP) hydrogen from shifted raw gas (Courtesy of Celanese and Lurgi AG)

The selective process is used *with two separate absorption steps* for raw and converted gas from oil and coal gasification by partial oxidation processes. Absorber – stripper systems (Fig. 41) are used to remove small quantities of carbon dioxide and hydrogen sulfide as integral parts of low-temperature units.

Plants with a one train throughput of more than 15.6×10^6 m^3 (STP)/d are already operating. The utility requirements for a Rectisol unit vary widely depending on process conditions. Typical consumption figures for selective removal of hydrogen sulfide and carbon dioxide from raw gas, yielded by partial oxidation relative to 100 000 m^3 (STP)/h (H_2 and CO) are

Power for drive shaft (without power recovery)	2000 – 2500 kW	
Steam (0.5 MPa)	5 – 7 t/h	
Waste heat above 110 °C	$33 - 42 \times 10^6$ kJ/h	using absorption
Cooling water (Δt = 10 °C)	1500 – 2000 m^3/h	refrigeration
Methanol	60 – 70 kg/h	

The application of the Rectisol Process for hydrogen production and for Integrated Gasification Combined Power Cycles (IGCC) [176]is described in 5.4.2.4(see Sections 7.2 and 7.3).

Processes with Other Physical Solvents. The Rectisol process needs a refrigeration unit to maintain the low absorption temperatures. Other processes employ organic solvents with high boiling points and low vapor pressures. These solvents provide a high absorption capacity for acid gases at ambient or slightly subambient temperature without appreciable vapor losses.

Although higher absorption temperature lowers carbon dioxide solubility, at a high partial pressure of carbon dioxide the loading capacity of organic solvents is still attractive and similar to the capacity of chemical solvents under comparable conditions.

Processes using high-boiling organic solvents are

1) Selexol process developed by Allied Chemical Corporation (now licensed by Norton and UOP) and the Genosorb process of Clariant and Krupp Uhde, all using a mixture of dimethyl ethers of polyethylene glycol (DMPEG);
2) Purisol process, developed by Lurgi, using *N*-methyl-2-pyrrolidone (NMP);
3) Fluor solvent process using propylene carbonate (PC);
4) Morphysorb process developed by Krupp Uhde using *N*-formylmorpholine (NFM);
5) Sepasolv process by BASF applying a mixture of oligoethylene glycol methyl isopropyl ethers (MPE); and
6) the Gaselane process using *N*-methylcaprolactam (NMC) developed by VEB Leuna [178]

The normal boiling point of these solvents is between 200 and 350 °C; their relative molecular mass, between 100 and 320. The solubility of carbon dioxide is similar for all solvents.

If selective removal of hydrogen sulfide from gas containing carbon dioxide is required, NMP is superior to Selexol, Sepasolv, and propylene carbonate. The solubility of carbonyl sulfide in all solvents is remarkably lower than the solubility of hydrogen sulfide.

This means that if these processes are used to purify gases containing both carbonyl and hydrogen sulfides to synthesis gas quality, a carbonyl sulfide hydrolysis step is generally required. With regard to removal of carbon dioxide from sulfur-free synthesis gas, the process flow sheet is basically the same for all processes, consisting of a simple absorber – stripper system. In addition to nitrogen or other inert gases, air is a suitable stripping medium.

Selexol Process [177]. This process was developed by Allied Chemical Corporation and is now licensed by Norton and UOP. The Selexol solvent is a trademark of the DOW Chemical Company and consists of a mixture of dimethyl ethers of polyethylenglycol (DMPEG). A similar mixture of DMPEG is used as solvent in the Genosorb process of Krupp Uhde and Clariant (solvent supplier). More than 50 Selexol plants had been constructed by 2005 purifying more than 110×10^6 m^3/d (STP) of natural gas and synthesis gas. Most commercial applications of the Selexol process are for treating natural and synthesis gas with high contents of hydrogen sulfide and carbon dioxide or high concentrations of carbon dioxide alone [175]. To purify gases containing carbon dioxide and hydrogen sulfide, the process may be used for either bulk removal of both components or selective removal of hydrogen sulfide, with the desired quantity of carbon dioxide being retained in the lean gas. Whereas the solubility of hydrogen sulfide is approximately nine times that of carbon dioxide, the solubility of carbonyl sulfide is only twice that of carbon dioxide.

This means that the difference in solubility between hydrogen sulfide and carbon dioxide is large enough to provide a good basis for selective absorption of the former. The solubility difference between carbonyl sulfide and carbon dioxide, on the other hand, is less favorable.

If carbonyl sulfide must be removed together with hydrogen sulfide, the solvent picks up more carbon dioxide and the feed to the Claus unit will be diluted with more carbon dioxide than for removal of hydrogen sulfide alone. Hydrolyzing carbonyl sulfide upstream of the absorption process can circumvent this problem. Nearly total conversion of carbonyl to hydrogen sulfide can be attained by vapor-phase catalytic hydrolysis, leaving only hydrogen sulfide and carbon dioxide as key components.

A certain amount of water in the Selexol solvent does not greatly decrease the solubility of

acid gases. Thus, in the case of hot regeneration by reboiling under normal pressure, the boiling point of the solvent can be decreased by addition of a suitable quantity of water.

A disadvantage of the Selexol solvent is that its lower boiling components are distilled off. Care must be taken that solvent properties do not change in the course of time.

The Selexol process is applied for following purposes:

1) Selective removal of hydrogen sulfide from natural gas and synthesis gas
2) Removal of high carbon dioxide content to a low residual level from natural gas and synthesis gas
3) Purification of landfill gas

Purisol Process. The Purisol process applies a mixture of NMP and water as solvent. It can be operated either at ambient temperature or — in conjunction with a refrigeration unit — at temperatures down to ca. − 15 °C. The Purisol process has been operated successfully for several decades in selective natural gas desulfurization and bulk CO_2 removal from converted synthesis gas. The process has the advantage of a higher hydrogen sulfide – carbon dioxide selectivity than Selexol, permitting the production of sulfur-rich Claus gas with about 50 % hydrogen sulfide, even if the ratio of carbon dioxide to hydrogen sulfide in the raw gas reaches extremely high values.

The solubility of carbonyl sulfide is only 20 % that of hydrogen sulfide, but the former is partly hydrolyzed to the latter by the NMP solvent resulting in a 60 – 80 % carbonyl sulfide removal. If the absorber is designed with carbonyl sulfide reaction zones, COS can be removed quantitatively. The absorption of valuable gas components is approximately 10 % lower compared to Selexol. Therefore a smaller amount of flash gases has to be recompressed.

For carbon dioxide removal, the NMP solvent can be regenerated with air, if nitrogen is not available. The carbon dioxide concentration in the purified gas can be reduced to 1000 ppm or less, with almost no steam demand for regeneration.

A typical example of a Purisol unit for removing carbon dioxide from converted gas is shown in Figure 48. Two identical units of this type operate in the same plant, treating synthesis gas for hydrogen production.

Pre- and afterwash steps are shown for both the absorber and the stripper in the flow sheet of Figure 48. Initially, raw and stripping gases are dried with a small amount of NMP to keep the water content of the solvent in the carbon dioxide absorption section low. A water wash on top of the columns reduces NMP losses. In general, NMP recovery with water is not necessary if the Purisol process is operated at subambient temperature. If a low water dew point of the product gas is required, NMP can be recovered by means of a glycol afterwash step.

The water – NMP mixture is separated in a third column, which simultaneously recovers NMP from the carbon dioxide off-gas at the flash stage. Carbon dioxide itself reduces the boiling point of the NMP – water mixture, which is a desirable effect.

Applications. The Purisol process is excellently suited to fours typical applications for high-pressure gases:

1) Selective removal of hydrogen sulfide
2) Removal of high carbon dioxide content to a low residual level
3) bulk removal of acidic compounds down to moderate product purity by using a simplified flash regeneration system, and
4) Removal of organic sulfur components (mercaptans)

Fluor Solvent Process. In the late 1950s, the Fluor solvent process using propylene carbonate was commercialized by Fluor and El Paso [180]. Removal of carbon dioxide from natural gas at mildly subambient temperature was the first application. The main criterion for selecting PC in the Fluor solvent process was its high carbon dioxide solubility, together with a relatively low solubility of methane. Propylene carbonate has limited water solubility, and slowly reacts irreversibly with water and carbon dioxide around 90 °C. Thus, it is unsuitable for controlling the water content by distillation under atmospheric pressure. Pre- or afterwash steps are, therefore, not applicable.

Morphysorb [181, 182]. Krupp Uhde applied their experience with *N*-formyl morpholine (NFM) as solvent to develop the Morphysorb process for selective sulfur compounds removal and bulk CO_2 absorption. Lower meth-

Figure 48. Purisol process for CO_2 removal from high pressure converted gas
a) Absorber; b) Stripper; c) NMP-water separator

ane solubility compared to other commercial solvents is claimed. NFM has a freezing point of 23 °C. To take advantage of the higher acid gas solubility at lower temperatures a mixture of NFM and *N*-acetyl-morpholine (NAM) is proposed.

5.4.2.2. Chemical Absorption Processes

Amine Processes. Aqueous amine solutions have been used on an industrial scale for the absorption of carbon dioxide and hydrogen sulfide for a long time. They are especially suited for gases with low organic sulfur content and less stringent purity requirements regarding hydrogen sulfide, as for example natural gas of pipeline quality or fuel gases. Synthesis gas qualities with total sulfur contents below 1 mL/m^3 require an additional sulfur adsorption guard bed downstream of the amine absorber.

Mono- and diethanolamine (MEA, DEA), as well as diglycolamine (DGA, 2-(2-aminoethoxy)ethanol), diisopropanolamine (DIPA), and methyldiethanolamine (MDEA), are well known in this field. Several so-called formulated amines are available on the market such as Ucarsol, Gas-Spec, and aMDEA (see Table 28). These solvents contain specific additives in order to allow higher amine concentrations, to enhance carbon dioxide absorption rate and to reduce corrosion potential and foaming tendency. The selectivity of the solvent towards hydrogen sulfide can be improved by sterically hindered amines such as Flexsorb SE.

Alkanolamines can be regarded as derivatives of ammonia in which one, two, or three hydrogen atoms have been replaced by a C_nH_{2n}-OH group. According to the number of organic groups attached to the nitrogen atom they are classified as primary, secondary, and tertiary alkanolamines. The primary alkanolamines applied for gas treating contain one ethanol group (MEA) or one glycolic group (DGA) The secondary alkanolamines employed contain two ethanol (DEA) or isopropyl alcohol groups (DIPA). MDEA as an *N*-alkylated alkanolamine has two ethanol groups and one methyl group attached to the nitrogen. The amino group provides the necessary alkalinity in the water solution to absorb the acid gases. The hydroxyl group in the alcohol moiety increases the water solubility and reduces the amine vapor pressure.

In the amine processes the acid gas components react reversibly with the alkaline solvent. The reactions of hydrogen sulfide and carbon dioxide with amines can be represented as follows:

Reaction of amine and water (protonation):

$$R_1R_2R_3N + H_2O \rightleftharpoons R_1R_2R_3NH^+ + OH^-$$

Sulfide formation:

$$H_2S + R_1R_2R_3N \rightleftharpoons R_1R_2R_3NH^+ + HS^-$$

Carbamate formation:

$$CO_2 + 2\,R_1R_2R_3N \rightleftharpoons R_1R_2NCOO^- + R_1R_2R_3NH^+$$

Bicarbonate formation:

$$CO_2 + OH^- \rightleftharpoons HCO_3^-$$

Hydrogen sulfide reacts instantaneously with all amines to form sulfide. Carbon dioxide can only react with primary and secondary amines to form carbamate. The carbamate reaction rate has a moderate velocity. The bicarbonate formation is slow. The different reaction rates of hydrogen sulfide and carbon dioxide with the amines are the basis for selective hydrogen sulfide absorption. MDEA has a higher selectivity compared to primary and secondary amines since no carbamate is formed with tertiary amines and carbon dioxide can only be absorbed via the slow bicarbonate reaction. In order to utilize this selectivity based on the reaction kinetics, the absorber must provide sufficient mass transfer area for complete hydrogen sulfide removal in combination with short residence time to suppress carbon dioxide absorption [183].

When the temperature of the solvent is increased and the pressure reduced, the chemical equilibrium of the above equations is shifted to the left side and the acid gases are released.

The flow diagrams for all amine process are basically the same (Fig. 49). Feed gas is brought in contact with the solvent in an absorber (a). Laden solvent flows through a heat exchanger (d) to the regeneration system (e), in which acid gases are desorbed from the solvent at reduced pressure with vapor generated by reboiling. Acid gases leave the regenerator overhead after the stripping steam has condensed (f). Regenerated solvent is returned to the absorber by way of the solvent heat exchanger (d) and solvent cooler (b). Amine losses with the lean gas have to be reduced by a water wash step. If the absorption operates at elevated pressure it is often economical to recover the absorbed valuable gases in an additional flash stage downstream of heat exchanger (d).

The amine concentration determines the capacity of the solvent and thus the solvent circulation rate. The maximum amine concentration of the solution is limited with regard to corrosivity of the rich solvent, viscosity, and other properties. Alkanolamines are susceptible to degradation by several trace components present in the raw gas and by carbon dioxide. Carbon dioxide catalyzes the degradation of MEA and DEA to form heat stable salts and inactive polymer reaction products, which increase solvent viscosity and foaming tendency. DIPA reacts with carbon dioxide to form oxazolidone. The capacity of the primary and secondary amines has to be maintained by continuous solvent reclaiming. MDEA as tertiary amine and hindered amines, which do not form carbamates, are not affected by carbon dioxide.

Figure 49. Basic flow diagram for amine processes
a) Absorber; b) Solvent cooler; c) Solvent pump; d) Heat exchanger; e) Regenerator; f) Condenser; g) Reboiler

Carboxylic acids (e.g., formic acid, acetic acid, oxalic acid) are frequently found in amine solvents. They are formed directly from cyanide and by degradation of the amine with oxygen. At high carbon monoxide partial pressure formic acid is directly produced in alkaline solutions. Carboxylic acids tie up amines as heat stable salts (HSS). Sulfur dioxide also reacts irreversibly with the amine to form HSS. Heat stable salts reduce solvent capacity and are a major source of corrosivity [184]. Common practice is the addition of caustic soda to liberate the amine and to restore solvent capacity. The effect of caustic addition on the corrosivity of the solvent is small because the acid anions remain in the solution [185]. The salts of the carboxylic acids have to be removed by ion exchange or distillation.

Primary Amines. Solutions of *MEA* were used almost exclusively for many years to remove hydrogen sulfide and carbon dioxide from natural gas and certain synthesis gases because of their high reactivity and the high purity obtainable.

The disadvantages of MEA are the formation of nonregenerable and corrosive degradation products with carbonyl sulfide and carbon disulfide. Because of the high vapor pressure of MEA a water wash step of the purified gas is normally required. The high heat of reaction causes high steam demand for hot regeneration. Thus MEA units are rapidly being replaced by other systems. However, the MEA solution is still preferred for gas streams containing small amounts of hydrogen sulfide and carbon dioxide with practically no carbonyl sulfide or carbon disulfide (e.g., the removal of carbon dioxide from reformed gas produced in a tubular reformer).

Newly developed corrosion inhibitors allow aqueous concentration of 30 wt % MEA, which results in a lower solvent circulation rate. An example is the Amine Guard process from Union Carbide. The Amine Guard process is suitable only for removal of carbon dioxide because sulfur components react with the inhibitors.

DGA is used in Fluor's Econamine process. The high DGA concentration (typical 40 – 60 wt %) reduces the required solvent circulation rate compared to MEA. Carbonyl sulfide is partially removed from the gas and the degradation products of DGA can be reclaimed at elevated temperature. No water wash step is required due to its lower vapor pressure [186].

Secondary amines DEA and DIPA are widely used to treat refinery gases and high pressure natural gases.

DEA is applied in the 20 – 25 wt % concentration range for refinery applications. DEA is superior to MEA for treating of refinery gases, which contain appreciable amounts of carbonyl sulfide and carbon disulfide, because DEA reacts with these components to a much lesser extent and the reaction products are less corrosive. The *SNEA-DEA process* for natural gases was developed by Societé National Elf Aquitaine (SNEA) [187]. A 25 – 30 wt % DEA solution is used resulting in higher solvent capacity. Acid gas loadings up to 0.7 – 1 mol/mol of DEA is possible with sufficiently high acid gas partial pressure. The heat of reaction of DEA and carbon dioxide is about 25 % lower than that of MEA and carbon dioxide. Therefore, DEA solutions require less steam for hot regeneration.

The *ADIP process* of Shell International Oil Products, licensed by JGC, Stork Engineers & Contractors, and Chiyoda [188], utilizes DIPA in concentrations up to 50 wt %. ADIP units are suitable for sweetening natural gas, refinery gas, and Claus tail gas. MDEA is also used in ADIP units if higher hydrogen sulfide selectivity is required. DIPA is claimed to be more stable against degrading and corrosive trace components like cyanide, oxygen, and sulfur dioxide than MDEA [212]. Therefore in cases where selectivity is not critical, DIPA is the preferred solvent for hydrogen sulfide removal. Raw gas purification and Claus tail-gas treatment can be integrated into one plant (Fig. 50). One single regeneration column (d) provides lean amine solvent for the fine wash section of the high pressure absorber (a) and the Claus tail-gas absorber (e). The tail-gas absorber operates at low pressure and hydrogen sulfide has to be removed selectively to avoid a large carbon dioxide recycle through the Claus plant. Therefore the rich solvent leaving the tail-gas absorber is not completely saturated and can absorb acid gas in the lower section of the high pressure absorber (a).

Hydrogen sulfide concentrations in the purified gas below 5 ppm (mL/m^3) are achievable with DIPA since it is easier to regenerate with less steam than MEA and DEA. DIPA has a lower tendency to form corrosive degradation products than DEA.

Tertiary Amines. MDEA is the most widely used tertiary amine. It is suitable to purify a large variety of gases. The carbon dioxide absorption rate is slower in tertiary amines because they do not form carbamates This makes MDEA particularly suited for selective hydrogen sulfide removal from gases with elevated carbon dioxide contents. Many formulated MDEA based amines are available on the market, which are claimed to have improved hydrogen sulfide selectivity (e.g., Gas Spec, Ucarsol) [189]. The low heat of reaction facilitates regeneration down to low acid gas contents in the lean amine required to achieve hydrogen sulfide concentrations below 5 mL/m^3 in the purified gas. MDEA is applied in the 30 – 50 wt % range. Acid gas loadings up to 0.8 mol/mol of MDEA is possible in carbon steel equipment. The high MDEA concentration in conjunction with the high attainable acid gas loading result in a high capacity of the solvent and a low solvent circulation rate. For this reason many amine units originally designed and operated with primary or secondary

Figure 50. Integration of high pressure gas purification with Claus tail-gas treating

amines were converted to use MDEA as solvent in order to increase plant capacity and reduce utility consumption [190]. As a guideline, the steam required for regeneration per volume solvent is approximately 80 kg/m^3 for bulk carbon dioxide removal and 120 kg/m^3 for selective hydrogen sulfide removal.

MDEA is widely used in refineries for hydrogen sulfide absorption from various medium- to high-pressure off-gas streams from hydrotreating units and the hydrocracker. MDEA is also suitable for selective absorption of hydrogen sulfide from low-pressure gases and is therefore applied in the Claus tail gas treating process.

The carbon dioxide absorption rate in MDEA solutions is enhanced by addition of small amounts of primary and secondary amines [191]. This effect is employed for example in the aMDEA process of BASF and the activated MDEA process of Elf Aquitaine. The carbamate formed with the activator component is hydrolyzed, giving bicarbonate and recovering the activator. The consecutive carbamate formation and hydrolysis reactions are much faster than direct bicarbonate formation with water.

Activator-carbamate reaction:

$$CO_2 + R_1R_2NH \rightleftharpoons R_1R_2NCOO^- + H^+$$

Carbamate hydrolysis:

$$R_1R_2NCOO^- + H_2O \rightleftharpoons R_1R_2NH + HCO_3^-$$

Part of the absorbed carbon dioxide can be liberated from aqueous MDEA solution by pressure reduction. Flash regeneration is sufficient if only bulk carbon dioxide removal is required. Lower carbon dioxide concentrations in the purified gas are achievable with an additional fine wash section, which has to be fed only with a small stream of steam regenerated solvent (Fig. 51). This makes the activated MDEA process attractive in terms of steam consumption. A typical aMDEA plant for the removal of carbon dioxide from steam reformer gas is shown in Figure 52.

The largest acid gas absorbers were built for a liquefied natural gas (LNG) terminal with a single train capacity of 1.6×10^6 m^3(STP)/h. Production of LNG requires bulk removal of all sulfur and carbon dioxide to avoid freezing in the liquefaction units. The aMDEA process of BASF is used to remove simultaneously hydrogen sulfide and carbon dioxide to the low ppm level. Additional molecular sieve adsorbers trap organic sulfur components such as mercaptans.

Degradation products of MDEA are secondary and primary amines, which also serve as activator for carbon dioxide absorption. Therefore in selective MDEA applications the carbon dioxide absorption is often higher than expected.

Sterically Hindered Amines. Solvents based on sterically hindered amines are licensed by Exxon Research and Engineering Co. under the trade name *Flexsorb* [192, 193]. These sterically hindered amines are secondary amine molecules bearing one bulky side group. This steric hindrance reduces the carbamate reaction rate by more than an order of magnitude compared to secondary amines. The basicity of this hindered secondary amine is higher than that of MDEA resulting in a higher hydrogen sulfide absorption capacity. Therefore, very high selectivity is attained in absorbers with short contact time [194].

Flexsorb SE solvent is a strongly hindered amine designed for high hydrogen sulfide selectivity [195]. It is therefore best suited for gases with high carbon dioxide: hydrogen sulfide ratio and in applications where low carbon dioxide absorption is required, such as Claus tail-gas treating. The benefits of Flexsorb have been demonstrated in various low pressure retrofit applications. Higher gas throughputs were achieved with lower solvent circulation rates compared to the original solvent. In addition the steam requirement for regeneration is reduced due to the lower solvent circulation rate.

With *Flexsorb SE Plus* hydrogen sulfide concentrations as low as 10 ppm (mL/m^3) at atmospheric absorber pressure are possible at the cost of 25 % higher circulation rates relative to Flexsorb SE. Acid buffer is added to the solution, which facilitates solvent regeneration.

Hot Potassium Carbonate Process. The potassium carbonate process has been successfully applied for carbon dioxide removal since 1960. The hot potassium carbonate process (HP) uses a potassium carbonate concentration in aqueous solution of 20 – 40 wt %. The reaction with carbon dioxide that occurs in the process also shows an equilibrium behavior that is favorable to absorption even at elevated temperature. As a result of the high absorber temperature (near the atmospheric boiling point of the solution), relatively low heat input is required for regeneration by reboiling.

Figure 53. Typical flow diagrams of the HP process for CO_2 removal
A) Single stage; B) Single stage with splitflow; C) Two stage process

Investment costs are lower than for MEA and DEA because solvent heat exchangers are not required. Figure 53 shows three typical versions of the process. The single stage type (Fig. 53 A) can be varied by cooling part of the solvent to lower the vapor pressure of carbon dioxide so that a higher purity of the treated gas can be obtained (Fig. 53 B). A carbon dioxide content of less than 0.5 % in the treated gas can be obtained economically only by using a two-stage design (Fig. 53 C).

The main application of the HP wash is removal of carbon dioxide from converted reforming gas, because process conditions are almost ideal for this. The carbon dioxide partial pressure after conversion is normally in the range of 0.4 – 0.7 MPa and, therefore, in the optimum range for equilibrium behavior of the solution (see Fig. 42, line e). In the production of hydrogen and synthesis gas for ammonia, a methanation stage follows as a fine purification stage for converting carbon monoxide and carbon dioxide residues. This step is operated at high temperature and in the presence of water, as in carbon monoxide conversion. This is in keeping with the high absorption temperature, as well as the aqueous solvent basis of the HP process. In view of the 0.25 – 0.4 % carbon monoxide in the gas downstream of the shift conversion, the gas in the absorption stage does not have to be cleaned to a carbon dioxide content of less than 0.1 %. The converted gas contains enough steam to cover the heat requirements of the HP process.

Figure 54 shows a characteristic working diagram for a two-stage HP absorption process. In addition to the equilibrium curve, which is practically identical for absorption and regeneration, operating lines of the absorber and the regenerator, together with determination of the theoretical stages according to McCabe – Thiele, are shown. The slopes of the operating lines are determined by the split fraction of semi-lean and lean solvent. Optimum adjustment of the split fraction results in the minimum number of theoretical stages required.

The process is available in different versions. Modifications differ less in the basic principles of the process than in the additives used as corrosion inhibitors or activators to increase mass transfer.

Modifications. The *Benfield process* uses mainly solutions with 25 – 30 % potassium carbonate and vanadate as an additive. Several developments have led to its widespread commercial application, especially with regard to ammonia plants based on natural gas and naphtha [196].

The solution used in the *Catacarb process* contains proprietary additives. Amine promoters enhance mass transfer rates and inhibit corrosion in applications such as purification of ammonia synthesis gas, hydrogen production, and natural gas. If no carbon dioxide is present a solution of potassium borate is used for hydrogen sulfide removal instead of potassium carbonate.

Figure 54. McCabe – Thiele diagram for a two-stage HP process

The *Lurgi HP process* uses borate as an additive, which accelerates absorption and is effective as a corrosion-inhibiting compound. In this process modification, both carbonyl and hydrogen sulfides can also be absorbed in the hot potassium carbonate solution. In the *high-purity version*, for example, hydrogen sulfide is removed to < 1 ppm. It can be absorbed selectively against carbon dioxide under certain conditions because of their different reaction velocities. The selectivity, together with other properties of the HP process (high absorption temperature, low investment and utility costs), is particularly advantageous for purifying coal gasification gas to fuel gas quality. Because coal gas usually contains additional impurities that cannot be removed in an HP wash, a precleaning step is required (see Section 5.4.4).

The regeneration operates under vacuum in the *Vacasulf process* of Krupp Uhde. The process is mainly applied for low pressure desulfurization of coke oven gas. Stringent lean gas qualities are achieved by a fine wash step with caustic soda.

Absorption in Ammonia Solution and Caustic Soda. Desulfurization with *ammonia solution* to purify gases containing ca. 500 mg of hydrogen sulfide per cubic meter was formerly very common for treating coke oven gas and is still used in some cases. However, the process has not become established for cases with more stringent purity requirements. On the other hand, it is an integral part of new developments for separating hydrogen sulfide – carbon dioxide and ammonia for sulfur recovery from sour gases containing ammonia, and for recovering ammonia from gas condensates.

Absorption of carbon dioxide and hydrogen sulfide in *caustic soda* produces bicarbonate and bisulfide the bonding of which is so strong that the vapor pressure of the sour components practically disappears. Therefore, gas purities as low as 0.1 mL/m^3 (CO_2 and H_2S) or less can be attained. However, regeneration, which is possible in principle but very complex, is dispensed with. Caustic soda is thus used only for fine purification.

5.4.2.3. Physical – Chemical Absorption Processes

Processes utilizing a solvent mixture of a physical organic component and a chemically acting component are termed physical – chemical absorption processes or mixed solvent processes. Mixed solvents provide a higher capacity than the pure physical solvent because of the additional chemical bonding of the acid gases with the chemical acting constituent. Fewer stages are normally required in the absorber due to the acceleration of mass transfer by the chemical reaction. The physically acting constituent of the mixed solvent provides absorption capacity for trace components such as carbonyl sulfide and organic sulfur components, which can not be removed with aqueous amines.

The best known processes are the Shell Sulfinol process and the Lurgi Amisol process.

Sulfinol Process. The Sulfinol solvent is a three-component solution containing the following constituents: an alkanolamine, usually

DIPA (diisopropanolamine), sulfolane (tetrahydrothiophene dioxide), and water. The ratio of the constituents varies according to the requirements of the application. The process, introduced in 1964, was used in its early years to remove hydrogen sulfide and carbon dioxide from gasification gases in steam reforming, as well as from natural gases [197]. More than 180 plants are reported to be in operation in 1998.

The process displays many properties and advantages of both chemical and physical processes. Acid gas loading is higher at elevated pressure and less steam for regeneration is required compared to purely chemical solvents. The physical character of the solvent facilitates to achieve hydrogen sulfide concentration as low as 1 ppm (mL/m^3) in the purified gas. Sulfinol is capable of removing other sulfur compounds including mercaptans, carbonyl sulfide, and carbon disulfide. The process flow sheet is very similar to chemical absorption processes (Fig. 49). Flashing of the rich solvent is often included as additional step to recover valuable gases and to increase the hydrogen sulfide concentration in the Claus gas.

The *Sulfinol-M process* uses MDEA instead of DIPA as chemical constituent in the solvent. This process can be designed for selective hydrogen sulfide absorption while a large percentage of the carbon dioxide from the raw gas slips to the treated gas.

Amisol Process. The Amisol solvent consists of an alkanolamine, normally MEA or DEA, in conjunction with methanol. This solvent mixture was successfully used in the first commercial Amisol plant in the early 1970s to remove carbon dioxide, hydrogen sulfide, and carbonyl sulfide from raw gas produced in a partial oxidation plant handling vacuum residues [198]. A clean gas with very low total sulfur content (hydrogen sulfide, carbonyl sulfide, mercaptans) of < 0.1 mL/m^3, as required for synthesis gas, can be obtained by the Amisol process. Good absorption of trace components such as hydrogen cyanide, and higher hydrocarbons is also achieved. Because of the low boiling point of methanol, absorption and regeneration temperatures are not far apart; therefore, no lean – rich solvent heat exchangers are normally required. Selective removal of both carbonyl and hydrogen sulfides versus carbon dioxide is possible by using *aliphatic alkylamines* such as diisopropylamine (DIPAM) and diethylamine (DETA) [199].

The Amisol process is suitable for treating various raw gases to absorb hydrogen sulfide, carbonyl sulfide, and carbon dioxide along with trace contaminants or to selectively remove sulfur compounds versus carbon dioxide. An example of a commercial Amisol plant using diethylamine involves purification of coal gas produced by an entrained-bed gasifier. A concept was developed for clean fuel power stations.

Flexsorb PS. The Flexsorb PS solvent is a mixture of a moderately hindered amine, a physical solvent, and water. This solvent is primarily suited for natural gas clean up. More than 95 % of carbonyl sulfide and mercaptans can be removed from the gas.

5.4.2.4. Comparison of Various Absorption Processes for Hydrogen Production and IGCC

Hydrogen Production Based on Residue Oil Gasification (see also 7.2)**.** Refineries require large amounts of hydrogen for hydrotreating and hydrocracking to meet stringent fuel specifications and to process heavier opportunity crude oils. The residues from visbreaker or hydrocracker units are an inexpensive feedstock for hydrogen production by gasification. The carbon monoxide from the raw gas is converted to hydrogen in a CO shift unit and the resulting raw hydrogen must be purified from acid gases and trace impurities. The selection of the appropriate gas purification technology depends on the required hydrogen purity, the value of the fuel gas and CO2 byproducts, and the plant emission regulations.

Acid gases must be removed from the raw hydrogen downstream of the sulfur-tolerant shift unit. This can be achieved with various processes.

In the first case (see Fig. 55A), the Rectisol process produces an H_2S-rich sour gas suitable for the Claus unit. In addition, CO_2 bulk removal is economical and a pure CO_2 stream is generated which can be used for sequestration or as industrial gas, or vented without further treatment. A pressure swing adsorption (PSA) unit is

Figure 55. Gas purification options for hydrogen production from gasification of heavy residue oil
A) Rectisol-based acid gas removal and PSA for hydrogen fine purification; B) Selective acid gas removal and PSA for hydrogen purification; C) Acid gas fine removal by Rectisol and methanation for hydrogen purification

used to free the hydrogen from impurities such as methane, nitrogen, carbon monoxide, and argon, which are concentrated in the PSA off-gas. The PSA off-gas is a high-BTU, low-sulfur gas, since Rectisol removes besides H_2S also economically virtually all the CO_2 and other trace acid components.

In the second case (see Fig. 55B) a selective acid gas removal (AGR) process is applied such as Purisol or Selexol, which also produces an H_2S-rich sour gas suitable for the Claus unit. Typically, 20–30 % of the CO_2 content of the raw gas is removed in a selective gas purification process. This CO_2 is produced as a separate, impure CO_2 stream with a significant sulfur concentration. The sulfur impurity in the CO_2 stream is normally not a problem for sequestration purposes or enhanced oil recovery. Simple venting, however, is usually not permitted.

Since AGR is selective, a considerable amount of CO_2 passes to the PSA unit in this case and is separated there. The PSA unit also separates the remaining sulfur impurities. Due to the high CO_2 content the PSA off-gas has a low heating value. It also contains a significant amount of sulfur because both Selexol and Purisol leave traces of H_2S in the low ppm range in the purified gas and remove carbonyl sulfide (COS) only partly.

In the third case (see Fig. 55C), if hydrogen production is to be maximized but high purity is not required and additional fuel gas is of low value, the PSA unit can be replaced by a methanation reactor which converts CO and CO_2 to methane. Since all impurities end up in the product hydrogen, the gas purification unit must remove all sulfur species to the ppb level and remove bulk CO_2 to the low ppm range. Rectisol is the process of choice for this configuration. Hydrogen purity exceeding 97 % can be achieved, which is normally sufficient for hydrotreating and hydrocracking applications, and no fuel gas is produced. This process configuration gives the highest specific hydrogen production.

Gas Purification for Power Production by Combined Cycle IGCC. In an integrated gasification combined power cycle (IGCC), fuel gas produced by partial oxidation of coal or residual oil is used to power a gas turbine (see 7.3). A gasification process is advantageously applied which recovers the energy of the hot gas leaving the reactor in a waste-heat boiler to produce high-pressure steam. The heat recovered from gasification and the exhaust gas of the gas turbine are utilized for a steam cycle (see Fig. 56). If the IGCC is installed in a refinery, additional hydrogen can easily be produced. Part of the desulfurized gas downstream of the acid gas removal is passed to a CO shift unit and the hydrogen is purified in a PSA unit.

Due to mechanical restrictions gas turbines usually operate at pressures below 30 bar, whereas gasification and gas cleaning operate advantageously at pressures above 50 bar. Higher operating pressures have the benefit of smaller equipment size. Additionally the increased solubility of the sulfur compounds in the

Figure 56. Cogeneration of power (IGCC) and hydrogen WHB-waste-heat boiler, AGR-acid gas removal, HRSG-heat recovery steam generation, PSA-pressure swing adsorption, MARS-metal/ash recovery system

absorbing solvent at higher pressure results in a lower solvent circulation rate that reduces utility demand for regeneration and solvent cooling.

The pressure difference between gasification and gas turbine can be utilized for additional power generation by expansion of the purified gas downstream of gas cleaning in a gas expander (see Fig57c). During expansion with power generation the gas temperature is reduced considerably. The expanded cold gas can be used for solvent cooling (d). The Rectisol process can be advantageously used for fuel gas production due to its ability to remove all sulfur components, including carbonyl sulfide. The required cooling to low temperatures can be done completely by the cold gas downstream of the expansion, if the pressure difference between gasification and gas turbine is high enough.

A comparison of a process with low-pressure gasification, gas purification, and gas turbine and a process with high-pressure gasification and gas cleaning, gas expansion, and low-pressure gas turbine is compiled in Table 29. The calculation is based on a residual oil gasification of 100 t/h and a net electrical power generation of 500 MW. Capital expenditures only for the gas cleaning unit are increased by 17 % by the gas expansion equipment, but for the complete IGCC plant the capital expenditures are increased only by 2 %. The utility demand is decreased by 13 %, and this leads to an overall increase of the electrical power generation efficiency of the IGCC from 45.4 to 46.2 %.

Table 29. Comparison of low pressure IGCC and high pressure IGCC with gas expansion

	High pressure gas cleaning with expansion	Low pressure gas cleaning
Gasifier pressure	58 bar	24 bar
Gas turbine pressure	22 bar	22 bar
Utility consumption		
Cooling water for gas cleaning	180 m^3/h	1230 m^3/h
Steam for regeneration	8.6 t/h	13 t/h
Electrical power for gas cleaning	− 0.4 MW	8.1 MW
Electrical power for air separation	32.6 MW	29.1 MW
Total electrical power	32.2 MW	37.2 MW
Capital expenditures (relative)		
Gas cleaning unit	117	100
Complete IGCC plant	102	100
Efficiency of electrical power generation		
Overall efficiency	46.2 %	45.4 %

An off-gas-free selective desulfurization for fuel gas production within an IGCC applying a selective absorption process such as Selexol and Purisol is shown in Figure 58. This process configuration operates successfully in an IGCC plant in Italy based on heavy residue gasification. Undesired trace components of the gasification such as cyanides or higher hydrocarbons are removed in a prewash stage (a). The rich solvent of the main wash is flashed in the reabsorp-

tion column (c). Carbon dioxide and valuable components are recovered as fuel gas, whereas hydrogen sulfide is reabsorbed in the solvent in order to increase the hydrogen sulfide concentration in the sour gas to the Claus unit. The fuel gas leaving the reabsorption column overhead can either be recompressed and added to the high-pressure purified gas or can be used as low-pressure fuel gas for the steam boiler of the IGCC. The typical sulfur recovery rate of a two-stage Claus unit is 95 - 96 %. The off-gas of the Claus unit contains beside unconverted hydrogen sulfide considerable amounts of SO_2 and COS, which are converted to hydrogen sulfide in a catalytic hydrogenation step. The hydrogenated off-gas is compressed and fed to the reabsorption step of the acid gas removal unit.

So-called zero-emission IGCC (Fig. 59) is discussed in view of the Kyoto protocol for reducing carbon dioxide emissions. In addition to total sulfur removal, carbon from the feedstock is also captured and concentrated in a second pure carbon dioxide product stream. The fuel gas to the gas turbine is pure hydrogen. The gasification process converts the carbon of the feedstock mainly to carbon monoxide, which is further converted to carbon dioxide and hydrogen in a carbon monoxide conversion unit (→ 5.1). The carbon dioxide can easily be separated from the hydrogen in the absorption process and

Figure 59. "Zero-emission" IGCC concept WHB-waste-heat boiler, AGR-acid gas removal, HRSG-heat recovery steam generation, PSA-pressure swing adsorption, MARS-metal/ash recovery system

a pure carbon dioxide stream is produced, which can be used for industrial purposes such as urea production, for enhanced oil recovery, or can be sequestered for carbon dioxide emission control. The economically achievable carbon recovery rate and the purity of the carbon dioxide product stream depend on the selected absorption process. The Rectisol process allows the production of ultralow-sulfur fuel gas (hydrogen) to the gas turbine and generation of very pure carbon dioxide. Selective-solvent processes such as Selexol and Purisol leave more sulfur in the fuel hydrogen. As expressed by the designation selective, this type of solvent requires greater effort for removal of bulk carbon dioxide. In addition, the carbon dioxide product stream contains larger amounts of hydrogen sulfide. Chemical absorption processes are not particularly suitable for removing these large amounts of carbon dioxide due to the large amount of steam required for solvent regeneration.

5.4.3. Liquid-Phase Oxidation Processes

In liquid phase oxidation processes hydrogen sulfide is absorbed from a gas stream in a liquid solution and directly oxidized to sulfur in the solution. The overall reaction can be expressed as follows:

$$H_2S + 1/2\,O_2 \rightarrow S + H_2O$$

The oxidizing agent in the solvent is reduced and solid sulfur is formed in the gas liquid contactor. In the subsequent regeneration step the solution is oxidized with air converting the oxidant to its oxidized state.

The main process steps are shown in Figure 60. The feed gas is contacted with the redox solution in a suitable gas – liquid contactor such as a countercurrent packed bed absorber, a spray tower, a cocurrent sparged tower, or a venturi scrubber. The sulfur formation takes place in the absorber and is completed in a downstream reaction vessel which may also serve as gas – liquid separator if the absorber works in the cocurrent mode. In the oxidizer the active component is converted from the reduced to the oxidized state and the sulfur particles are separated either as froth by flotation or as slurry by settling. The regenerated solution is recycled to the gas – liquid contactor. The sulfur froth or slurry is either separated in a filter unit or a sulfur melter.

Liquid-phase oxidation processes are especially suitable for selective removal of hydrogen sulfide versus carbon dioxide, because carbon dioxide does not react with the redox solution. Essentially complete hydrogen sulfide removal with concentrations below 1 ppm (mL/m^3) in the treated gas is attainable. Contrary to physical or chemical absorption processes in which the off-gas of the regenerator must be generally treated

Figure 60. Schematic flow diagram of liquid phase oxidation processes

in an additional unit to produce sulfur or sulfuric acid, in liquid-phase oxidation processes the formation of elemental sulfur occurs within the purification unit itself.

The main applications of liquid-phase oxidation processes are

1) Desulfurization of coke oven gas, natural gas, and synthesis gas with low hydrogen sulfide concentration,
2) Treatment of gases that cannot be processed economically in a Claus plant (e.g., due to low hydrogen sulfide concentration, small total amount of sulfur),
3) Treatment of Claus tail gases,
4) Replacement of dry purification processes, and
5) Treatment of very low raw gas rates (e.g., landfill gas).

Economical operation is limited to sulfur production rates less than 20 t/d due to high utility costs. Continuous solvent make-up is required because the solvent is susceptible to chemical and thermal degradation and because of losses with the sulfur filter cake. Continuous solvent purging is required due to the accumulation of side products such as thiosulfate in the solvent circulation. Thiosulfate production can be kept below 1 % of the hydrogen sulfide converted, if operating conditions such as temperature and solution pH are carefully controlled. A buffering agent in the solution avoids large pH swings due to carbon dioxide absorption.

Carbonyl sulfide and organic sulfur components are only partly removed in liquid oxidation processes. Hydrogen cyanide and sulfur dioxide are almost quantitatively absorbed and react to thiocyanate and sulfate in the solution. These salts accumulate in the circulating liquor and increase the required purge stream and the amount of hazardous waste byproducts generated. Ammonia is also absorbed and causes pH changes. Ammonium polysulfide is formed with solid sulfur, increasing the salt concentration in the solution. Ammonia is stripped in the oxidizer and may cause odor problems in the vent stream.

Sulfur quality is often not crucial because of the small amount of sulfur produced. Residual solvent impurities have to be removed from the filter cake by washing with demineralized water. An additional sulfur washing and melting step is required to achieve sulfur quality similar to Claus plant sulfur.

A drawback of all liquid-phase oxidation processes is the relatively low oxidation capacity of the solution for hydrogen sulfide. This necessitates large solvent circulation rates. The heat of reaction generated by the oxidation of hydrogen sulfide must be dissipated at low temperature and cannot be used, as in the Claus process, to generate valuable steam. Only part of the heat of reaction can be used for the heat demand of the process.

The development of liquid phase oxidation processes started with iron oxide suspended in aqueous alkaline solutions (e.g., Ferrox, Gluud, and Manchester). The second generation of processes applied thioarsenate (e.g., Thylox, Giammarco–Vetrocoke [200]). They have lost market acceptance because of the toxicity of the solution. An aqueous mixture of vanadium pentoxide, naphthoquinone, and alkali carbon-

ate is the basis of the widely used *Stretford* process [201], the *Takahax* process [202] and the *Sulfolin* process. Presently, environmental concerns about the vanadium content in the purge stream have resulted in the selection of iron chelate-based processes such as *Lo-Cat* [203], *SulFerox* [204] and *Sulfint* [205] for most applications. Processes using sulfur dioxide are *Townsend* [206] and *IFP Clauspol* [207]. In the end they have not been commercially successful. A new class of processes apply microorganisms to convert hydrogen sulfide to sulfur (e.g., Shell-Thiopaq [208] and Bio-SR).

Vanadium-Based Solutions. The *Stretford* process, originally developed for the removal of hydrogen sulfide from coke oven gas, has proved to be equally suitable for desulfurization of other gas streams such as natural, synthesis, and tail gases.

The Stretford process uses an aqueous solution containing sodium carbonate, sodium bicarbonate, anthraquinonedisulfonic acid (ADA), and sodium metavanadate. The process can be considered to proceed in the following steps:

1) Absorption of hydrogen sulfide in the alkali solution,

$$H_2S + Na_2CO_3 \rightarrow NaHS + NaHCO_3$$

2) Oxidation of hydrogen sulfide to sulfur by sodium metavanadate,

$$4\,NaVO_3 + 2\,NaHS + H_2O \rightarrow Na_2V_4O_9 + 2\,S + 4\,NaOH$$

3) Reoxidation of the reduced vanadate by ADA

$$Na_2V_4O_9 + 2\,NaOH + H_2O + 2\,ADA \rightarrow 4\,NaVO_3 + 2\,ADA\,(reduced)$$

4) Oxidation of reduced ADA by air in the regenerator

$$2\,ADA\,(reduced) + O_2 \rightarrow 2\,ADA + 2\,H_2O$$

Figure 61 shows a simplified flow diagram of the Stretford process for selective desulfurization. The raw gas is brought in contact countercurrently with the solution in the absorber (a) and purified to a level of < 1 ppm of hydrogen sulfide. The solution flows from the absorber bottom to the reaction vessel (c) to complete the conversion of hydrogen sulfide to elemental sulfur; then the solution is regenerated in the oxidizer (d) by contact with air.

Sulfur is separated by flotation and removed at the top of the oxidizer (d) as froth containing 5 – 10 % solids. The sulfur froth is collected in a vessel and subsequently processed in a filter or centrifuge. The sulfur has to be washed with water to separate solution and sulfur and to produce relatively pure sulfur. Though installed in numerous commercial plants, the Stretford process suffers from the drawbacks of formation of byproducts and environmental concern about vanadium in the effluent streams.

In the solvent used in the *Sulfolin process* ADA is replaced by an organic nitrogen vanadium promoter [209]. Like the Sulfolin process the *Unisulf process* [210] claims a reduced formation of byproducts and lower corrosivity, resulting in lower chemical consumption.

Iron-based Solutions. Iron is kept in the aqueous solution by organic ligands or chelating agents (L). The basic chemistry in the iron chelate solution can be summarized as follows:

Absorption:

$$2\,Fe^{3+}L + H_2S \rightarrow 2\,Fe^{2+}L + S + 2\,H^+$$

Regeneration:

$$2\,Fe^{2+}L + 1/2\,O_2 + 2\,H^+ \rightarrow 2\,Fe^{3+}L + H_2O$$

In iron chelate processes sulfur is generally separated by settling. The slurry containing 10 – 15 wt % sulfur is further processed by filtration in order to recover the solvent. Stainless steel equipment is required due to the high solvent power of the solution for iron.

The *Lo-Cat* process is licensed by U.S. Filter. The flow sheet of the conventional Lo-Cat process is similar to the SulFerox process shown in Figure 63. Oxidation of the rich solvent and sulfur settling take place in the same vessel. The solution contains up to 0.3 wt % iron resulting in large solvent circulation rates with high power demand for solvent pumping especially in high pressure gas purification.

In the Lo-Cat *autocirculation design*, hydrogen sulfide absorption, the conversion to sulfur, and the oxidation of the redox solution take place in one vessel in separate compartments (Fig. 62). The autocirculation design is applicable for low pressure gases such as acid gases from amine units and Claus tail gases. Due to the compact design hydrogen sulfide is not totally

Figure 61. Schematic of a Stretford plant for selective H_2S removal
a) Absorber; b) Air compressor; c) Reaction vessel; d) Oxidizer; e) Solvent vessel; f) Sulfur filter

converted to sulfur before the solution is contacted with air. This causes an increase in the thiosulfate formation of up to 5 % of the converted hydrogen sulfide.

Figure 62. Lo-Cat autocirculation design

The Lo-Cat process operates with the stoichiometric ratio of iron(III): hydrogen sulfide of 2: 1. In the Lo-Cat II process the ratio of iron(III) to hydrogen sulfide is maintained at 1: 1. An improved solution chemistry enhances the reaction kinetics. The rich solvent from the absorber is mixed with oxidized solution upstream of the oxidizer. Residual HS^- in the rich solvent is thus totally converted to sulfur by iron(III) before the solution is contacted with oxygen resulting in thiosulfate formation below 1 %. Due to the substoichiometric operation less solvent has to be circulated to the high pressure absorber, reducing the power requirement for pumping. The Lo-Cat II process is also available in the autocirculation design.

The *SulFerox* process was developed by Shell and is licensed by DOW and Shell (Fig. 63). Special feature of this process is the high iron concentration of 2 to 4 wt %, reducing equipment sizes and pumping costs. The high iron concentration accelerates the reaction kinetics and thus the hydrogen sulfide absorption rate. One possible design for the absorption section is the patented cocurrent pipeline contactor with proprietary mixing elements which makes use of the fast reaction kinetics. Low pressure drop, nearly infinite hydrogen sulfide turndown capability, and low fouling tendencies are provided in a small diameter vessel. Due to the fast reaction kinetics all of the hydrogen sulfide absorbed is converted to sulfur and no HS^- ions are present in the rich solution when entering the oxidizer. Thiosulfate formation is claimed to be below 0.1 %.

The pH of the SulFerox solution is kept below 8. Carbon dioxide solubility in the SulFerox solution is therefore similar to that in water, resulting in a very high hydrogen sulfide selectivity. The SulFerox solution is also capable of removing about 70 % of mercaptans present in the raw gas.

A comparison between one of the amine processes plus Claus plant, autocirculation Lo-Cat, direct Lo-Cat, Lo-Cat II, and the SulFerox pro-

Figure 63. Schematic flow diagram of the SulFerox process. A) Absorber, b) Gas-liquid separator, c) Flash drum, d) oxidizer, e) Sulfur settling vessel, f) Sulfur filter (Courtesy of Shell International Oil Products B.V.)

cess in technical and economical terms was performed by the Gas Research Institute (GRI) [213]. Lo-Cat II and SulFerox perform very similar for the two high pressure gas cleaning cases studied. The two Lo-Cat modifications and an amine process plus Claus plant result in significantly higher sulfur production costs.

Biological Processes. Suitable bacteria convert hydrogen sulfide under certain conditions to sulfur. The processes consist of the same process steps as conventional liquid phase oxidation processes (Fig. 60). In the *Shell-Thiopaq process* hydrogen sulfide is absorbed into an iron-free caustic solution. The dissolved sulfide is subsequently oxidized to sulfur in the Thiopaq reactor by bacteria of the genus Thiobacillus. The *Bio-SR process* of NKK Corporation uses a nonchelated iron(III) sulfate solution. The bacteria act as catalyst in the oxidizer to enhance the kinetic of regeneration from iron(II) to iron(III) sulfate. Both processes have demonstrated to be capable for removing hydrogen sulfide from high pressure natural gases.

5.4.4. Removal of Gas Impurities of Low Concentration

Raw gases contain numerous gaseous impurities besides the acid gases. High boiling hydrocarbons have to be removed because of dew point specifications in the purified gas. Organic sulfur compounds are harmful to most catalysts. Unsaturated hydrocarbons tend to polymerize in the solvent circulation. Acids, hydrogen cyanide, and ammonia tend to form salts in the absorption solution. Gases from residual oil or coal gasification often contain volatile metal compounds such as mercury and metal carbonyls.

The absorption of impurities depends on the solvent. Higher hydrocarbons will only be partly absorbed in water-based amine solvents and cause foaming problems. Low-boiling impurities are trapped in organic solvents such as Selexol and Purisol and can not be removed by solvent stripping. Rectisol has the advantage that the impurities absorbed are purged together with the process water from the solvent loop. Although the concentration of impurities in the gas is often in the ppm range they may accumulate in the solvent circulation to levels that cause problems such as fouling, foaming, corrosion, and solvent degradation. Therefore they are often removed in a separate prewash process upstream of the acid gas removal.

Water Wash Process. Even a simple water prewash can remove acids, cyanide compounds, and ammonia very effectively from the gas, because their water solubility (e.g., expressed by the absorption coefficient) is very high (see Fig. 64).

However, high solubility also means difficult regeneration, especially because purity requirements of wastewater are stringent and fresh water is scarce. Therefore, the laden water must often undergo complex stripping with steam and impurities must then be incinerated.

Figure 64. Solubility of different gases in water at low pressure 0.1 MPa

Oil Wash Process. Hydrocarbons, especially the normally undesirable unsaturated ones that tend to polymerize, as well as saturated high-boiling ones, are best removed by using an oil wash, which generally is designed with a hot regeneration stage (see Fig. 41 C). Occasionally, the vapor pressure of the washing agent in the absorber is too high so that a higher boiling oil fraction must be used. If the boiling temperature of this fraction is too high, it cannot be boiled indirectly in the regenerator with steam but only directly with live steam or a fired reboiler.

In some types of raw gas — especially that generated from coal — removal of the main gas impurities can require a whole series of prewash steps before highly concentrated gas components such as carbon dioxide are separated and chemically converted. Examples are prewashes with water for hydrogen cyanide and ammonia, followed by absorption of hydrogen sulfide in aqueous ammonia. In a final fine wash step benzene, naphthalene, gum formers, and other unsaturated hydrocarbons are absorbed in an oil wash.

Rectisol Prewash. The previously described prewash systems were particularly important for raw gas produced from coal pressure gasification, which contained almost all the impurities named, extending to gas naphtha. Therefore, attempts were made to find a simpler solution to this problem, which succeeded in conjunction with the development of the Rectisol process: all impurities are removed with only one solvent, methanol, which is also used downstream for removal of hydrogen sulfide and carbon dioxide.

Figure 65 shows a simplified scheme of such a prewash in which only a small quantity of cold methanol removes water, hydrogen cyanide, ammonia, gum formers, gas naphtha, and other impurities from the raw gas. Methanol is regenerated by extraction with water and two-stage distillation.

Condensation. Low boiling substances and water have to be removed from natural gases to meet pipeline dew point specification. This is often accomplished by condensation at low temperature. The *Ifpexol* process (Fig. 66) of Institut Français du Petrol (IFP) removes water and recovers liquid hydrocarbons from raw natural gas [211]. Part of the raw gas is brought into contact with a methanol rich stream in the methanol stripper (a). The methanol concentration in the water leaving the stripper as bottom product can be reduced to 50 mg/kg. The methanol vapor in the overhead raw gas prevents hydrate and ice formation in the gas chiller (b). The liquid condensate is separated in a settler vessel (d) into the liquid hydrocarbon fraction and the methanol – water fraction. The methanol – water fraction is recycled to the methanol stripper. The pretreated gas can be further purified by any suitable process.

Mercury Removal. Mercury emissions from coal-based power plants are of environmental concern. Conventional coal-fired power stations have to treat a huge volume of flue gas in an activated-carbon adsorber. Power production based on coal gasification (IGCC) allows easier removal of mercury. The Rectisol process

Figure 65. Rectisol prewash for raw gas from coal
a) Extraction system; b) Azeotropic distillation column; c) Methanol – water distillation column

Figure 66. Gas pretreating by condensation with Ifpexol process. a) Methanol stripper, b) Gas chiller, c) Gas – liquid separator, d) Liquid – liquid separator

for acid gas removal also traps mercury with no additional adsorption step required. Other absorption processes require an additional activated carbon guard bed, which has to treat the smaller amount of fuel gas to the gas turbine.

5.5. Adsorption Processes

5.5.1. Fundamentals (→ Adsorption)

Three types of adsorbents are particularly suitable for the adsorption of gaseous components in fixed beds on an industrial scale:

1) activated aluminum oxide or silica gel,
2) molecular sieves, and
3) activated carbon.

Apart from process conditions such as pressure and temperature, the degree of adsorption on the above-mentioned solids is determined also by the structure of the adsorbent and the properties of gaseous components, such as volatility and polarity. Adsorption of substances that are characterized by high volatility and low polarity — typical examples are hydrogen and helium — is very poor or almost imperceptible, whereas water and carbon dioxide, for example, are well adsorbed because of their low volatility and high polarity. If process conditions are near the dew point of a gas component, that component is adsorbed preferentially.

Adsorption Mechanisms. The qualities of adsorbents are attributable in part to their characteristic material structures. Activated carbon (→ Carbon, Chap. 5), for instance, traps and retains gas molecules in minute pores measuring only a few molecular diameters.

In addition to this minipore effect, water molecules are adsorbed on silica gel or activated aluminum oxide in the form of water of crystallization, filling vacancies in the crystal lattice. In the case of molecular sieves (→ Zeolites), electrostatic forces come into play in addition to the minipores and surface-enlarging micropores, increasing their adsorption capacity, especially for polar and polarizable gases.

Adsorption Conditions. A look at adsorption processes in the molecular range suggests that these effects are improved by increasing process pressure and decreasing temperature.

For a particular gas and a selected adsorbent, adsorption capacity B is shown in Figure 67 as a function of pressure p at varying temperature T. This group of curves, which is characteristic of each adsorbate and adsorbent, cannot be calculated quantitatively but must be determined by empirical means.

Basic Modes of Operation in Adsorbent Beds. Figure 67 also shows the basic modes of operation possible for a fixed-bed adsorber. Three possibilities exist:

Figure 67. Adsorption capacity B of adsorbents as a function of pressure and temperature

First Basic Mode of Operation: Path 1 – 2. At T_0 and p_0, the adsorbent is loaded to the degree B_1. If the temperature T_0 is kept constant and the pressure is increased from p_0 to p_1, the adsorbent can collect the higher load B_2. The difference $B_2 - B_1$ is the adsorption capacity, which can be used for *pressure-swing adsorption* (PSA).

Second Basic Mode of Operation: Path 3 – 4. While the pressure is kept constant at p_1, the temperature is reduced from T_2 to T_{14}. This operation forms the basis of a *temperature-swing adsorption* (TSA) process.

Third Basic Mode of Operation: Path 4 – 5. This classic method of adsorption and regeneration uses the low temperature T_1 and high pressure p_1 for adsorption, and then regenerates the system by decreasing the pressure to p_0 and increasing the temperature to T_2 by heating. The adsorption capacity, described by the difference $B_4 - B_5$, is clearly the highest of the three cases.

Possible Applications. For gas conditioning, the adsorption of gases on fixed beds has three possible applications:

1) elimination of undesirable trace impurities from gas mixtures,
2) removal of contaminating gaseous components to yield a highly pure finished product, and
3) separation of substances.

Industrially useful applications can be derived only from an appropriate combination of gas components to be adsorbed and effective adsorbents. The following text describes a few typical processes used in practice.

5.5.2. The "Classic" Method

The classic method (third mode of application, above) may be illustrated by means of the removal of water and carbon dioxide traces.

If gas mixtures such as hydrogen – carbon monoxide, hydrogen – methane, nitrogen – methane, or air are separated into their individual components in cryogenic processes, traces of water and carbon dioxide will lead to icing and clogging of equipment. For this reason, such substances must be removed completely from the gas mixture at ambient temperature.

High carbon dioxide contents in the gas mixture are normally reduced by chemical or physical wash processes (see Section 5.4) to a level determined by the optimum arrangement of the wash process with a view to efficient subsequent adsorption.

The moisture content of the gas — as shown in the example in Figure 68 — can be significantly decreased by lowering the temperature to near the freezing point (ca. + 5 °C). The water and carbon dioxide traces remaining in the gas mixture can then be adsorbed efficiently and completely on a fixed bed.

Process Description. As shown in Figure 68, most carbon dioxide is removed from the gas mixture in a carbon dioxide scrubber, and the gas is cooled to ca. +5 °C. Condensed water is then removed in a downstream gas separator.

Loading Period. The gas mixture containing a residual quantity of 100 – 150 ppm of carbon dioxide and water is fed to adsorber (a), flowing through it from bottom to top. For water adsorption, adsorbers (a) and (b) may be filled with activated aluminum oxide, silica gel, or molecular sieves. The latter have been found most effective for adsorbing carbon dioxide. After carbon dioxide and water have been removed, the gas is fed to the cryogenic section.

Partial Regeneration by Flashing. At the same time, the pressurized adsorber (b) is isolated from the gas flow at working temperature and depressurized to regeneration pressure. The gas in the adsorber is lost to the process. Adsorbed water and carbon dioxide, which are liberated from the adsorbent as the system is depressurized, are removed from the adsorption bed by the regeneration gas flowing in the opposite direction to the gas flow during adsorption.

Fine Regeneration by Reheating. To complete regeneration, the adsorber bed is purged with hot regeneration gas containing neither water nor carbon dioxide. In the process, the adsorbent is heated to ca. 250 – 300 °C. It is then recooled with cold regeneration gas in the final stage. Regenerated adsorber (b) is pressurized again with clean process gas and can be used for another adsorption cycle.

Changeover. When adsorber (a) has been fully loaded, the gas flow is switched to adsorber (b) while adsorber (a) is regenerated.

Process Conditions. The gas composition and the length of the adsorption – regeneration cycles determine the size of the adsorption unit. The following conditions in particular must be met: (1) The total quantity of impurities in the gas mixture must not be too large so that the adsorbent volume — and, along with it, the size of the adsorbers — as well as the recycled regeneration gas rate are kept within reasonable limits. (2) The adsorbent quantity must be adequate for the adsorption stage to ensure that the heating and cooling time is sufficient for the required amount of regeneration gas during the simultaneous regeneration stage. With this arrangement, the adsorption and regeneration cycles normally require 4, 6, or 8 h.

Other Applications of the Classic Adsorber Loop. The system is also used to adsorb traces of water from gases before they are sent through pipeline systems. Moisture is an undesirable ballast, leading to corrosion along with carbon dioxide, hydrate formation with methane, and freezing when cooled. The maximum allowable moisture content, normally specified for water dew points from −5 to −30 °C, can be achieved for small or moderate gas flow rates at reasonable cost with adsorber units that use activated aluminum oxide, silica gel, or molecular sieves in long adsorption cycles, as well as the classic method of regeneration. Natural or town gas may be dried in this way before being fed to the gas grid. Similarly, adsorbers are

Figure 68. Reversible adsorber unit to eliminate residual carbon dioxide and water
a) Adsorber; b) Adsorber; c) CO_2 scrubber; d) Chiller; e) Gas separator; f) Cooler; g) Heater; h) Regenerator gas; i) Cryogenic process

used to adjust the residual moisture content of the control air, instrument air, and compressed air used in plants to a dew point normally of −25 to −30 °C.

5.5.3. Pressure-Swing Adsorption (→ Adsorption, Chap. 7.2)

The principle of the PSA process can be illustrated by the recovery of highly pure hydrogen. If a gas mixture containing hydrogen passes through a bed of molecular sieves at elevated pressure and ambient temperature, these sieves preferentially adsorb the high-density and polar gas components. Hydrogen, being the component least amenable to adsorption, remains alone in the gas phase, provided the adsorber bed is large enough for the gas rate flowing through it.

Process Description. At least two adsorbers are required to ensure continuous production of highly pure hydrogen. While one adsorber is in the adsorption stage, the other is regenerated by depressurization.

To purge the adsorbent bed, the flashed gases are discharged from the bed in the opposite direction to the flow during the adsorption stage. In this way, the pure gas released toward the end of the regeneration stage expels from the adsorber those components that are adsorbed first during the adsorption stage. The regenerated adsorbent bed is repressurized with pure product gas or with the gas mixture to prepare it for the next adsorption stage.

Process Conditions. Depressurizing and repressurizing adsorbers requires less time than heating and cooling the adsorbent bed during classic regeneration. Therefore, keeping the adsorber mass, and hence also the vessels, small by using short adsorption – regeneration cycles is cost-effective. Cycles between 5 and 10 min are efficient in practical applications. However, a drawback of the process is that one vessel volume of recoverable hydrogen is lost during each regeneration phase when the adsorber is flashed. This is why yields of highly pure hydrogen are generally poor relative to the recoverable hydrogen content of the gas mixture.

Special Process Loops. To improve the yield, the number of adsorbers may be increased from two to four, six, or ten.

In principle, these adsorbers or adsorber groups simultaneously operate in the following four modes (→ Adsorption):

1) adsorption in the first adsorber,
2) depressurizing the second adsorber,
3) purging the third adsorber at low pressure, and
4) pressurizing the fourth adsorber.

With this loop, losses of recoverable hydrogen are reduced by using the gas released when the second adsorber is depressurized to repressurize the fourth adsorber to medium pressure.

Product Purity. A four-adsorber loop can yield hydrogen of 99.999 % purity and produces a uniform product flow, achieving yields as high as 72 – 78 % of the hydrogen in the gas mixture. The types and quantities of contaminants in the gas mixture influence the size of the adsorber beds and, to a certain extent, the yields. However, they do not influence the function of the pressure-swing adsorption unit or the purity of the recovered hydrogen. Contaminants are discharged at ambient pressure together with the hydrogen used for purging. In the last ten years, this process has been used in several plants designed for an output up to 100 000 m^3 (STP)/h of highly pure hydrogen.

Multicomponent Separation [214]. Further developments of current adsorption processes aim, on the one hand, at improving the adsorbents and optimizing process loops and adsorption – regeneration cycles and, on the other, at utilizing various desorption effects depending on the respective components. In the past, adsorption processes were tailored to recover one product in a highly pure form (e.g., H_2 from gas mixtures, O_2 or N_2 from air). Modern developments take advantage of the different properties of individual components during desorption to increase the content of certain components in the outgoing flows. To this end, the origin of the desorption flash gas is considered, for example, raw gas from the inactive volume of the vessel and the intergranular volume, raw gas from the pore volume, and desorbed gas from the inner surfaces of the adsorbent at various desorption pressures (medium pressure, normal pressure, vacuum). The upgrading effect is reinforced by suitable process arrangements during desorption (e.g., cocurrent or countercurrent desorption), in combination with the passing of adsorbed gases to other adsorbent beds.

This process arrangement can be used successfully to separate gas mixtures consisting of hydrogen, carbon monoxide, and carbon dioxide into highly pure product hydrogen, a carbon monoxide fraction, and a residual gas fraction with an increased carbon dioxide content. Analogously, a mixture consisting of nitrogen, methane, and carbon dioxide can be separated into nitrogen waste gas, a high-methane fraction, and a carbon dioxide fraction. In both cases, the components participating in the process behave very differently because of their properties, not only during individual adsorption cycles but also during desorption cycles.

5.5.4. Adsorption on Activated Carbon

Activated carbon (→ Carbon, Chap. 5) shows a strong adsorptive effect because of its extensive pore system. Suitable preparation of carbonaceous materials can produce different pore structures, so that the distribution of pore radii may be matched to specific adsorption requirements. A variety of pore sizes down to micropores and minipores with diameters on the order of small gas molecules can be produced.

Applications. For gas purification, adsorption on activated carbon is used to protect downstream process stages or systems from traces of compressor lubrication oil or other low-volatility hydrocarbons, such as toluene and washing oil, which may have entered the gas flow through a special wash process. These adsorbers are characterized by high adsorptivity, especially for substances that are near their dew point or have been entrained with the gas flow in the form of minute condensate droplets. Activated carbon adsorbers can usually be regenerated by heating them and simultaneously purging the adsorbent bed with hot steam. Coking of the adsorbent, however, cannot be avoided entirely, so that the adsorption capacity of the activated carbon adsorber decreases with each regeneration cycle. Frequently, greater economy results from providing a single activated carbon bed of sufficient size, operating it to breakthrough, and refilling it with fresh activated carbon during a brief shutdown.

5.6. Cryogenic Processes (→ Cryogenic Technology)

Cryogenic processes are used to recover pure gas fractions from gas mixtures. Typical examples are *carbon monoxide* and *hydrogen*. The required purity of both products depends on their intended use. The accompanying substances and contaminants are more or less the same in all cases: hydrogen, carbon monoxide, carbon dioxide, residual methane, nitrogen, oxygen, argon,

steam, contaminants such as oils, saturated and unsaturated higher hydrocarbons, sulfur compounds, nitrogen oxides, and acetylene. Their concentrations vary according to the method used to produce the synthesis gas. Because the gas mixture is further processed, admixtures such as hydrogen or carbon monoxide, carbon dioxide or steam may lead to undesirable secondary reactions. Especially when unused gases are recycled to the process, nitrogen, argon and methane will lead to a build-up of inert components and thus impair the process conditions. Contaminants especially in the ppm range such as sulfur compounds, steam and acetylene, but also carbon monoxide in hydrogen, frequently poison the catalyst or produce secondary reactions at the catalyst.

In practice, a carbon monoxide product gas contaminated with not more than 1 – 3 % hydrogen, methane, or nitrogen meets the quality requirements for most downstream chemical processes. Hydrogen used for hydrogenation or ammonia synthesis must meet even more stringent purity requirements.

Sulfur compounds, acetylene, carbon dioxide, and water are removed from synthesis gas by washing, adsorption, and absorption. This reduces the problem to the recovery of pure hydrogen or carbon monoxide from a gas mixture essentially containing hydrogen, carbon monoxide, and methane. Cryogenic separation is a promising route, in addition to selective absorption and adsorption, for separating the components of this gas mixture.

Plant engineering has benefited from several cryogenic processes, and various process combinations have been used for the respective applications. Two principal process loops seem to be promising for *carbon monoxide* recovery from synthesis gas mixtures: (1) partial condensation and (2) the liquid methane wash process. A third process — the liquid nitrogen wash process — is used to recover *hydrogen* for ammonia synthesis.

5.6.1. Partial Condensation

The first stage of the partial condensation process for recovering hydrogen or carbon monoxide from synthesis gas mixtures is the liquefaction of higher boiling gas components such as carbon monoxide and methane. Depending on the pressure applied, liquefaction begins at ca. −100 to −180 °C, and ends when the sublimation temperatures of methane and carbon monoxide are reached.

The first components to liquefy in a hydrogen atmosphere are methane and carbon monoxide. Separation of the gaseous and liquid phases alone yields relatively pure product flows.

Because carbon monoxide recovery requires temperatures as low as −200 °C, for a cryogenic process to work properly all components that may freeze and clog the piping must be removed completely.

In partial condensation, carbon monoxide is condensed along "cold walls." This leaves a quantity of carbon monoxide, corresponding to the carbon monoxide vapor pressure, uncondensed. The "cold wall" is produced in a heat exchanger by flashing liquid carbon monoxide to the lowest possible pressure and evaporating it in countercurrent. This defines the coldest point of the partial condensation process: it is the temperature of liquid carbon monoxide evaporating at the lowest possible pressure [215, 216].

If the carbon monoxide condensate contains an unacceptably high percentage of methane, this must be removed by distillation. The carbon monoxide yield is 75 – 80 %. Losses are due to uncondensables in the hydrogen flow and to carbon monoxide removed along with methane. However, recovery of only part of the carbon monoxide may be desirable if hydrogen gas containing a certain proportion of carbon monoxide is required.

Process Description. Figure 69 shows a typical process flow diagram of a partial condensation unit. After all contaminants that might freeze and clog the piping have been removed from in a pretreatment stage, the gas mixture is cooled in heat exchangers (a) in countercurrent to the cold products coming from the plant. Part of the carbon monoxide and methane is condensed, and the gas and liquid are separated in a separator (b). Hydrogen gas, which still contains some carbon monoxide, is reheated. The liquid containing traces of dissolved hydrogen and methane is depressurized; dissolved hydrogen boils off and is removed in the downstream separator (c). The liquid, which no longer contains any hydrogen, is fed to a column (d) where the carbon monoxide – methane mixture is sep-

arated into pure carbon monoxide and a methane fraction containing a certain percentage of carbon monoxide. All cold products are evaporated at ambient pressure and heated in countercurrent to the hot incoming gas mixture. The carbon monoxide yield may be increased by modifying the process by additional process steps and recycling of carbon monoxide containing flash gases.

Figure 69. Cryogenic partial condensation process
a) Heat exchanger; b) Separator; c) Degasser; d) CO – CH_4 separator; e) Expander

In this process, hydrogen is obtained at its full pressure, which is not always required in a carbon monoxide recovery unit. The hydrogen produced can, therefore, also be used for flash refrigeration in an expander (e). This process element enables the coldest temperature to be lowered by ca. 20 to −200 °C, so that the amount of carbon monoxide remaining in the gaseous phase is greatly decreased and the carbon monoxide yield increased [215, 216]. Process results are given in Table 30.

Table 30. Typical analyses for the process flow diagram shown in Figure 69

	Feed gas	H_2 fraction	CO product	Residual gas
Without expander stage				
Analysis, mol%				
H_2	70	88	1.5	40
CO	27	12	98.5	50
CH_4	3			10
Volume parts	1000	650	50	300
With expander stage				
Analysis, mol%				
H_2	70	96.5	1.5	40
CO	27	3.5	98.5	50
CH_4	3			10
Volume parts	1000	600	100	300

5.6.2. Liquid Methane Wash Process

Liquid methane is used to wash a pressurized hydrogen flow slightly above the freezing point of methane (i.e., ca. −180 °C). During this process, carbon monoxide carried along with hydrogen is dissolved in methane; 100 % of carbon monoxide in the feed is recovered [217] so that hydrogen leaving the column overhead is free of carbon monoxide. For calculation methods applicable to isothermal wash processes, see [218].

Spent methane is regenerated by distillation, expelling carbon monoxide overhead. By using the heat pump principle and employing a flash refrigerator, carbon monoxide can be conveniently recycled and used to maintain the refrigeration balance.

Process Description (see Fig. 70). Pretreated synthesis gas is cooled in a heat exchanger (a) to the washing temperature of −180 °C. High-boiling components are thus condensed, and only the gaseous carbon monoxide in the hydrogen gas is washed out with methane in column (b). This washing methane, methane from the gas mixture, and carbon monoxide that has been condensed or washed out are fed to the carbon monoxide – methane separator (c). There, the carbon monoxide product is discharged overhead while the washing methane remains as the bottom product. A liquid methane pump (d) delivers the washing methane via a supercooler (e) to the top of the wash column (b), from which carbon monoxide-free hydrogen is discharged overhead. The product streams of carbon monoxide, hydrogen, and residual meth-

Figure 70. Liquid methane wash process

ane are heated in the exchanger (a), flowing in countercurrent to the feed gas, and recovered individually.

The carbon monoxide compressor (g) closes the refrigeration loop with the expander (f). The same compressor may also be used to adjust the carbon monoxide product to the required battery limit pressure. Process results are given in Table 31.

Table 31. Typical analyses for the process flow diagram shown in Figure 70

	Feed gas	H_2 fraction	CO product	Residual gas
Analysis, mol%				
H_2	70	98.5	1.7	
CO	27		98.5	
CH_4	2	1.5	0.1	100
Volume parts	1 000	705	275	20

5.6.3. Liquid Nitrogen Wash Process

A finishing treatment in a liquid nitrogen wash unit is the last process stage in the recovery of hydrogen for ammonia synthesis from hydrocarbons. In preceding stages, carbon monoxide is converted to carbon dioxide, producing additional hydrogen, and carbon dioxide is then eliminated completely from the synthesis gas. Hydrogen gas entering the liquid nitrogen wash unit contains the following undesirable substances and contaminants:

1) traces of unreacted oxygen from the gasification process,
2) residual methane from unreacted hydrocarbons,
3) some unconverted carbon monoxide, and
4) argon that entered the system together with the oxygen required for gasification

Whereas argon and methane in the synthesis gas are inerts and would unnecessarily burden the ammonia synthesis loop, the residual oxygen and carbon monoxide are poisonous to the ammonia synthesis catalyst. Except for an unavoidable residue of argon, the above-mentioned contaminants are all eliminated by means of a liquid nitrogen wash unit.

The refrigeration needed for this process is obtained by flashing the required amount of nitrogen for washing the synthesis gas into the purified hydrogen already in the cryogenic unit. By mixing the nitrogen with the hydrogen stream, the pressure of the cryogenic nitrogen is lowered from the full process pressure at which the pure nitrogen is cooled to the nitrogen partial pressure in the hydrogen stream, which more or less reflects the proportion of nitrogen (24 – 25 %) in the synthesis gas. Essentially, the positive excess enthalpy ΔH occurring during this process pro-

vides the refrigeration necessary for the entire process [219].

Figure 71. Liquid nitrogen wash unit
a) Heat exchanger; b) Wash column; c) Valve for wash nitrogen; d) Refrigeration valve; e) Trim valve

Process Description (see Fig. 71). Hydrogen gas containing contaminants such as oxygen, argon, carbon monoxide, and methane is cooled to ca. −180 °C in a heat exchanger (a). At a temperature around its dew point, the gas is fed to the bottom of the wash column (b). Liquid nitrogen trickling down countercurrently to the hydrogen gas dissolves the contaminants and is discharged with them from the bottom of the column. The overhead product is purified hydrogen with an nitrogen content that reflects the equilibrium stage of a hydrogen – nitrogen mixture at the of temperature and pressure prevailing at the top of the column. Nitrogen required in the wash unit is compressed to the process pressure, cooled in an exchanger (a), and fed to the wash column through a valve (c). Nitrogen needed for refrigeration is cooled in the same way, flashed through a valve (d) into the purified hydrogen, and evaporated in the exchanger (a) in countercurrent to the uncooled and untreated hydrogen and the nitrogen flow. The valve (e) is used to add nitrogen to establish the hydrogen – nitrogen ratio (3: 1) required for synthesis.

Wash nitrogen containing the dissolved contaminants is discharged from the column bottom, flashed to a lower pressure, evaporated, heated, and discharged as residual gas (for process results, see Table 32).

Table 32. Typical analyses for the process flow diagram shown in Figure 71

	H_2 gas	N_2 gas	Synthesis gas	Residual gas
H_2	94.11 mol %		75 mol %	8.31 mol %
N_2	0.05 mol %	100 mol %	25 mol %	26 mol %
O_2	ppm	ppm	2 ppm	ppm
Ar	0.60 mol %		50 ppm	7.14 mol %
CO	4.44 mol %		5 ppm	52.68 mol %
CH_4	0.50 mol %		10 ppm	5.87 mol %
Volume parts	1000	337	1253	84

5.7. Gas Separation by Membranes (→ Membranes and Membrane Separation Processes)

Fundamentals. Certain materials, when produced in the form of nonporous membranes of defined thickness, absorb gas components in their molecular structure at different rates and allow them to diffuse through the membrane with a certain pressure drop. The diffusion rate depends on (1) the type of material, (2) the size of the molecules, (3) the pressure differential across the membrane, and (4) the diffusion length (membrane thickness) and active area of the membrane. The following types of membrane can be distinguished:

Polymer membranes
Carbon membranes with micropores
Liquid membranes
Metallic membranes
Ceramic membranes

Whereas membranes based on ceramics, metals, and liquids have been known for a long time and have been developed to an industrial standard for some applications (e.g., palladium ceramics for the production of highly pure H_2), the development of polymer membranes for gas separation [220 – 225] has been accelerated since 1977 by the rapid development of reverse osmosis membranes for seawater desalination [226].

Several gas separation membrane systems, which compete in materials and design of the modules, can be found on the market:

1) *Prism separator* (Monsanto), an asymmetric porous membrane on a polysulfone carrier with a nonporous silicon-based coating, in the form of hollow-fiber bundles;
2) *Delsep* (Delta Engineering Corporation), an asymmetric porous membrane based on cellulose acetate with a nonporous cellulose acetate-based coating, in the form of a coil-type module with a flat membrane;
3) *Separex* (Air Products Company); and
4) *RO membranes* (DuPont), asymmetric porous membranes based on aromatic polyamide or cellulose acetate with a nonporous aramid-based coating, in the form of hollow-fiber bundles.

Applications. Hydrogen and helium have the best sorption and diffusion behavior of all gas components, and their separation efficiency is very good in comparison to nitrogen, methane, carbon dioxide, or carbon monoxide. Such gas separation units are, therefore, employed to recover hydrogen from reaction gas mixtures by using the same process principle as shown in Figure 72 in all cases.

Process Description. *Case 1: Gas Separation Membrane installed in a Slipstream.* Purge gas which must be extracted continuously from a synthesis gas loop (as installed for the ammonia production) to keep down the level of undesirable ballasts and nonreacting components essentially contains the same valuables as the loop (e.g., H_2, N_2, or CO). To improve overall efficiency of the synthesis loop, these valuables can be recovered by means of a gas separation membrane and recycled at low pressure to the suction side of the raw gas compressor. Those gas components that do not permeate the membrane (e.g., CH_4, Ar, CO, higher hydrocarbons) remain in the waste gas. Typical gas composition is shown in Table 33.

Table 33. Typical gas composition for purge gas treatment

	Raw gas	Permeate	Waste gas
H_2, vol %	74	96	57
CO, vol %	26	4	43
Flow rate, kmol/h	100	43.6	56.4
Yield		H_2: 56 %	CO: 93 %

Case 2: Gas Separation Membrane in the Main Stream. Hydrogen sulfide and carbon dioxide exhibit much better sorption and diffusion behavior than the product gases carbon monoxide and methane. This favorable separation efficiency can be used in a pretreatment stage to reduce the size of downstream conventional fine treatment (see Fig. 73). Most of the sour gases are removed by the gas separation membrane, although some valuable components are lost as well. Such losses of valuable components can be minimized by splitting the process into several stages and recycling the gases — a method which, of course, requires additional energy. Being preceded by a membrane, the absorption unit is turned into a fine treatment stage, whose dimensions and complexity can be reduced considerably.

5.8. Addition of Inerts or Other Substances

Normally, the quality of a gas is described not only by its composition but also by such characteristics as its calorific value and Wobbe index (see Chap. 8).

These characteristics are adjusted as necessary, either by adding inerts such as nitrogen or air to decrease the calorific value and increase the density of a gas, or by adding high-calorific substances such as liquefied gas, butane, or gasoline to increase the calorific value. Proper mixing is achieved by installing flow turbulators, providing spray injection of liquids into the gas stream, or adding densifiers.

If air is added, the oxygen level in the gas must be watched closely. Explosive air – gas mixtures, which may occur briefly in areas where air is injected into the gas, can be eliminated by flow turbulators.

If liquefied natural gas is used as feedstock, it can be conditioned to the required calorific value by adding liquefied nitrogen in the cryogenic liquid phase. Proper mixing is ensured as the gas evaporates at discharge pressure. This conditioning method saves energy because only a minimum of energy is required to pump the liquefied natural gas and liquefied nitrogen, rather than necessitating installation of compressor stations for natural gas, nitrogen, or the gas mixture.

Substances with a manifest odor—usually higher mercaptans—are added to normally odorless gases to warn of any leaks.

6. Handling of Byproducts

Cooling the crude product gas leads to the formation of aqueous and hydrocarbon condensates. Usually, water-insoluble hydrocarbons are removed from the aqueous phase and handled separately. Treatment of the condensates and the crude gas also results in gaseous byproducts.

6.1. Aqueous Condensates

Rates and Components. All production methods for gases containing carbon monoxide and hydrogen primarily generate a hot crude gas mixed with water vapor, regardless of feedstock. The water content of the crude gas originates

from the feedstock moisture (coal), unconverted gasification steam, or reaction water (oxidation of part of the feedstock hydrogen). Cooling the crude gas produces aqueous condensates laden to a greater or lesser extent with organic or inorganic substances, depending on the type of feedstock and the gasification method. Table 34 shows typical condensate rates and contents of dissolved or suspended components for some feedstocks and selected gasification methods. The numbers may change depending on gasification conditions. As a rule, condensate rate and impurity content increase with decreasing gasification temperature and increasing feedstock complexity [227 – 231]. In addition to the classical feedstocks nowadays a variety of waste materials are used. These have to be prepared, e.g., by pelletizing using suitable binders such as bituminous coal and/or by mixing with coal in certain ratios between 50 % and 85 %. The waste includes solid and liquid materials like plastics, sewage sludge, rubber, fluff, contaminated wood, residues of paint, household wastes, industrial waste, etc., as well as tar/oil from fixed bed gasifiers, used oils, solvents etc. [232]. This changes the composition of the condensates slightly. The modern practice is to select gasification types and conditions in such a way that the condensates obtained are as clean as possible and/or show low specific rates, in order to reduce the wastewater treatment cost (see Chap. 4).

Typical Specifications of Treated Wastewater. Condensates are recycled as far as possible within the gas production plant. Only excess condensate must be specially treated. Treatment methods depend on the final destination of condensates:

1) Use as boiler feedwater (liquid disposal),
2) Use as cooling water make-up (gaseous disposal),
3) Burning of contents and evaporation of water (gaseous disposal), or
4) Release to receiving water (liquid disposal).

The first two are possible only if the condensates contain easily removable components (e.g., using steam reforming condensate as boiler feedwater after degassing) or are cleaned by various treatment processes (e.g., using coal pressure gasification condensate as cooling water after tar – dust separation, filtration, extraction, stripping, adsorption, biological oxidation, etc.) [233, 234]. Burning is limited by the amount of water to be evaporated, the environmental impact of sulfur and nitrogen oxides, and economic aspects (proportion of recoverable heat). In practice, incineration of gas condensates has been considered only for small rates [235] or for the concentrated residues after treatment [236].

The last method is the most common: gas condensates are treated to meet wastewater specifications (local authority regulations) so that the effluent can be discharged into receiving water (river, canal, lake, sea).

No universal wastewater disposal standards exist. Specifications must be negotiated with the local water control authority, which usually considers the plant location, type of feedstock, conversion process, and type of receiving water [237, 238]. Typical wastewater specifications for authorized effluent disposal are listed in the following material [BOD_5 = biological oxygen demand (five days)], indicating the targets for various wastewater treatment processes described in the following sections.

Temperature	max. 30 °C
pH	6.5 – 8.5
Suspended solids	max. 30 mg/L
BOD_5	max. 30 mg/L
COD	max. 500 mg/L
Hydrogen sulfide	max. 0.1 mg/L
Ammonia (measured as nitrogen)	max. 200 mg/L
Free cyanide	max. 0.5 mg/L
CNS^-	max. 15 mg/L
Monohydric phenols	max. 0.1 mg/L
Total phenols	max. 10 mg/L
Substances extractable with petroleum ether	max. 20 mg/L

6.1.1. Mechanical Treatment

Gravitational Separation. Suspended solids such as soot, char, or ash and entrained tar or oil are removed mechanically from gas condensates. In coal pressure gasification plants, the first cleaning step is usually carried out in tar separators, often followed by additional oil separators. In oil gasification plants, soot is usually extracted with oil or naphtha and recycled to the process.

Table 34. Specific rates and composition of gas condensates

Process examples	Lurgi coal pressure gasifier	British Gas – Lurgi slagging gasifier	Texaco, Shell,Lurgi MPG	Steam reforming
Type	moving bed	moving bed	partial oxidation	catalytic
Feedstock	bituminous coal	bituminous coal	heavy vacuum residue	naphtha

COD, mg/L	25 000		2400	
BOD_5, mg/L	8000		1000	
Composition, mg/L				
Suspended solids	100		120	
Suspended oil	1000		20	
Free ammonia	15 000	20 000	1500	
Fixed ammonia	350	3 000	150	
CO_2	30 000	40 000	2400	400
H_2S	700	600	1600	
HCN	50	100	300	
Monohydric phenols	4500	4000	<1	
Total phenols	6000	5000	<1	
Dissolved organic substances	500			
Halides (Cl^-, F^-)	250	4000		
Fatty acids	800	500	400	
Nickel	0		2 – 5	
Iron	4		6 – 15	
Vanadium	0		3 – 8	
pH	8 – 9	8 – 9	8 – 9	5 – 7

Primary tar separators may be simple tanks provided with a feed nozzle, an expansion gas exit to release dissolved gases, an oil skimmer, and drawoffs for tar, solids, and cleaned water. Oil has a lower density, and tar – dust a higher density, than water so they form top and bottom layers that are withdrawn while water is obtained in the intermediate layer. The settling area of tar and oil separators is usually designed to remove all particles having a settling velocity higher than 1 – 3 m/h from the aqueous phase. Remaining particles are removed in the following filtration step.

Part of the mixture of tar and dust (heavy tar) is recycled to the gasifiers by positive displacement pumps. Excess tar sometimes undergoes further dust removal and is sold as a product. After primary tar separation, the gas condensate still contains up to 100 mg/L of solids and 500 – 5000 mg/L of tar and oil [239].

The gas condensate is cleaned further in *oil separators* down to a content of oil and solids in the range of 20 – 50 mg/L. The efficiency of these separators can be enhanced by fitting a large number of parallel corrugated plates, which not only increases the settling area but also achieves laminar flow conditions, resulting in low Reynolds numbers. An example of this separator type is the Shell CPI [240].

Filtration. The following treatment steps (e.g., extraction, stripping, adsorption) require that tar and solids content be reduced to 10 mg/L or lower. This can be done in simple gravel filters operated at low specific loads of ca. 5 – 7 $m^3\,m^{-2}\,h^{-1}$. Modern dual- or multimedia filters can operate up to 20 $m^3\,m^{-2}\,h^{-1}$. In dual-media filters, the gas condensate flows first through an upper layer of lower density, coarse filter media, which allows finer solids to penetrate deeply into the filter bed, and then through a lower layer of finer filter media to ensure final cleaning.

Filters operate batchwise. Filter beds loaded with tar and solids are regenerated by backflushing with (hot) water. Usually, the bed is also loosened by blowing gas through it. After cleaning, filter bed particles are classified according to Stokes' law by means of an upward stream of water at a defined rate. The filters not only remove solids to < 10 mg/L but, at low temperatures and low velocities, remove tar and oil as well. These partly stick to the filter media and partly collect in the bottom of the filter, from which they can be removed prior to backflushing. The backflushing liquid (mud liquor) is normally recycled to the primary tar separator.

Phenol	45
Cresols	30
Xylenols	6
Polyhydric and other phenols	10
Pyridine bases	1
Neutral oil, pitch	5
Water	3

6.1.2. Extraction and Adsorption of Organic Substances

Filtered gas condensates containing high levels of dissolved organic substances cannot directly be treated biologically. First, the phenol content must be reduced to an acceptable level, usually < 700 mg/L. At low feed rate or concentration, this is done by dilution. At high concentration of steam volatile phenols, the condensate is dephenolized prior to stripping the dissolved gases. This is carried out either by liquid – liquid extraction using organic solvents — e.g., benzene, methyl isobutyl ketone (MIBK), butyl acetate, or diisopropyl ether (DIPE) — or by adsorption on activated carbon. Combinations of these processes are also possible [241 – 243]. Adsorption on activated carbon is mainly used for posttreatment after dephenolization and/or biological treatment of condensates in gas production plants [244 – 246].

Phenol Recovery by Solvent Extraction. Figure 74 shows a typical phenol extraction process used in gasification plants, as well as in coke oven and carbonization plants, in the phenol industry, and in coal hydrogenation plants. In the Phenosolvan process the filtered and cooled phenolic effluent is treated countercurrently with a suitable solvent such as DIPE in a multistage extractor. The extract is separated by fractional distillation into pure solvent (overhead product) and crude phenols (bottoms product). The solvent is recycled to the extractor. The raffinate still contains a small amount of solvent which is recovered by stripping with recycled gas. The solvent is then removed from the gas by absorption in cooled and recycled crude phenols, from which it is subsequently recovered in the stripping section of the fractionator. The Phenosolvan process can be operated with different feedstocks, different solvents or solvent mixtures (e.g., benzene and DIPE or DIPE plus MIBK) [247], and different solvent recovery systems (e.g., steam, gas, or ammonia stripping). All steam volatile phenols and neutral oils can be recovered almost completely, but only partial recovery of pyridines, fatty acids, and dihydric phenols is possible. The suitability of this process for hard-to-extract organics is limited only by economics, because residual phenols and other organics can be removed more cheaply by adsorption or biological treatment. The intermediate phenol content between extraction and final treatment is best determined by means of an economic optimization study, an example of which is shown in Fig-

Figure 74. Lurgi Phenosolvan process for phenol recovery (with steam-saving solvent recovery by gas recycle)
a) Extractor (mixer – settler); b) Fractionator; c) Solvent absorber; d) Solvent stripper

ure 75. An advantage of solvent extraction is the recovery of crude phenol by fractionating the extract which contains valuable byproducts. Typical composition of a Phenosolvan extract from coal pressure gasification is given below, in percent by weight:

Figure 75. Economical phenol recovery point between phenol extraction and final treatment (typical, e.g., for coal gasification condensates containing ca. 4500 mg/L monohydric and ca. 1500 mg/L polyhydric phenols)
a) Extraction; b) Biological treatment; c) Total cost; d) Biological and activated carbon treatment

If large gas condensate flows must be dephenolized, extraction must be performed in mixer settlers, exhibiting high stage efficiencies. Lower flow rates can be treated in extraction columns by using many stages to compensate for low efficiency.

Recovery by High-Pressure Extraction. Organics can also be recovered by using supercritical solvents [248]. This method might be economical for small condensate rates with high feed concentrations of phenols and other valuable organics, but it is not yet being used in gas production plants [249]

6.1.3. Removal and Recovery of Ammonia and Sulfur

Before gas condensates rich in dissolved gases (NH_3, CO_2, HCN, H_2S) can be treated in biological oxidation or in heavy-metal precipitation plants, they must be stripped with gas or steam to decrease free ammonia to < 50 mg/L, hydrogen sulfide to < 1 mg/L or hydrogen cyanide to $<$ 10 mg/L, or to lower the pH (previously 8 – 9) to 6. This is done in the *total stripper* common to all removal or recovery processes. Its primary purpose is to produce stripped gas condensate as bottom product. The overheads contain all the free gases and water vapor. Processes differ in the method of treating this gas mixture.

Total Stripper. Depending on the major feed contaminant, this stripper has different names such as *ammonia still* and *sour water, hydrogen sulfide*, or *hydrogen cyanide stripper* [250]. It usually operates at normal atmospheric pressure, but the pressure may be adjusted depending on the destination of the top gases. Typical steam consumption is 140 – 250 kg of steam per cubic meter of gas condensate.

The stripper is usually equipped with a top condenser to reduce the water content of the gases from > 90 to $< 50\,\%$.

Incineration, Catalytic Oxidation and Sulfur Recovery. The mixture of ammonia, sour gases, and water can be flared off only if the environmental impact (e.g., of SO_2, NO_x) is acceptable. Otherwise, a special incineration plant with flue gas treatment is required. Ammonia can also be removed by catalytic oxidation [251].

If a Claus plant (→ Sulfur, Chap. 6) is available, the strip gas can be mixed with the feed for sulfur recovery and ammonia oxidation. If the ammonia flow is too high compared to the Claus sulfur stream, the strip gas must be divided into an ammonia-free sour gas and an ammonia stream low in hydrogen sulfide [252]. Both streams are fed separately to the Claus plant; first the ammonia stream is oxidized above stoichiometric conditions and then mixed with the sour gas stream at below stoichiometric conditions to produce sulfur. Any NO_x formed in the first step reacts with sulfur produced in the second step; thus, both sulfur dioxide and NO_x emissions are eliminated [253].

Recovery of Ammonia. If the ammonia quantity exceeds a certain level, incineration is unacceptable but recovery becomes economical compared to (catalytic) oxidation. Formerly, the strip gases were washed with sulfuric acid to obtain ammonium sulfate, and the remaining acid gases were fed to sulfur recovery plants. Because ammonium sulfate sales today are limited, the recovery of anhydrous or aqueous ammonia is preferred in most cases. Generally, two different methods are available for the difficult separation of basic and acid gases from aqueous solution:

1) Chemical methods using agents that selectively absorb ammonia under certain conditions, but release ammonia under regeneration conditions [254]; and
2) Physical methods (without agents), based on different vapor pressures of ammonia and acid gases at different concentrations in aqueous solution and at different temperatures or pressures [242, 255, 256][257].

The first method is represented by the Phosam-W process (U.S. Steel, USX Engineers & Consultants, Aristech Phosam-W), and the second by the CLL ammonia recovery process (Chemie Linz/Lurgi) or by the WWT process (Chevron); both types of processes are used in coal pressure gasification plants [258 – 261]. The largest plant worldwide for the recovery of clean liquid ammonia from coal pressure gasification wastewater operates in Secunda at Sasol II and III since 1980. Both CLL trains together have a total capacity of 1000 t NH_3 per day formed as a byproduct.

Phosam-W Process (see Fig. 76). The total stripper (a) overheads are treated in the ammonia absorber (b) with lean ammonium phosphate solution, which selectively absorbs ammonia under prescribed conditions. The wet overhead acid gases are dried (c) and sent to a sulfur recovery unit. The rich ammonium phosphate solution is regenerated in the Phosam stripper (d) at high temperature and recycled to the absorber. The stripper overheads (mainly ammonia and water) are condensed, treated with sodium hydroxide to bind coabsorbed acid gases, and fractionated to yield pure anhydrous ammonia as final product. Hot (475 K) fractionator bottom water and sodium hydroxide are flashed into the total stripper.

Figure 76. Phosam-W process for chemical separation of aqueous ammonia – acid gas mixture
a) Total stripper; b) Phosam ammonia absorber; c) Acid gas drier; d) Phosam ammonia stripper

Clean Liquid Ammonia Recovery Process (*CLL*; see Fig. 77). The total stripper (a) overheads are treated in the acid gas absorber (b) and ammonia stripper (c) column. Ammonia is cleaned by fractional condensation and fed to a liquefaction unit, to yield anhydrous ammonia as final product. Alternatively, ammonia can be absorbed in water or fed into the ammonia pipeline of the factory (Chemie Linz). The acid gas absorber bottoms are concentrated in the ammonia stripper (c) and fed to the deacidifier (d) where clean carbon dioxide and hydrogen sulfide are obtained as top product, suitable for use directly as sulfur recovery feed gas.

Deacidification is enhanced by dilution with water or elevation of temperature and pressure. Deacidified gas condensate is fed to the total stripper, closing the CLL loop.

The gas condensate is fed either to the deacidifier if it contains more acid gases and/or inert gases and/or traces of solvent from the dephenolization step or to the total stripper if it contains more ammonia. Diluted condensates are also fed to the total stripper.

Both processes described yield ammonia qualities comparable to synthetic ammonia (Table 35); hence, process selection depends on economic considerations.

Figure 77. CLL Ammonia recovery process for physical separation of aqueous ammonia – acid gas mixtures
a) Total stripper; b) CLL ammonia stripper; c) CLL acid gas absorber; d) Deacidifier

Table 35. Typical composition of anhydrous ammonia

	Clean liquid ammonia recovered from gas condensates	Synthetic ammonia
Water (added), wt %	0.01 – 0.2	0.2
Ammonia, wt %	99.99 – 99.8	99.8
Oil, ppm	<2	<5
Organic substances, ppm	<8	not determined
H_2S, ppm	<1	not determined
CO_2, ppm	<50	not determined

Economic Considerations. *Chemical absorption – regeneration plants* usually have low capital costs but high operating costs because of the use of stronger agents and the need for high-pressure steam to regenerate the chemicals. Chemical absorption plants are less flexible with respect to overload, since the agents have a distinct limit of loading capacity. *Physical absorber – stripper plants* have higher capital costs but lower operating costs because of the use of cheaper steam. The higher the gas condensate flow rate or the ammonia feed concentration, the more economical are physical methods; chemical methods are more economical in the case of low flow rates or low ammonia feed concentrations.

6.1.4. Biological and Final Treatment

After extraction and stripping, gas condensates still contain organic and inorganic substances such as fatty acids, dihydric phenols, and anions (e.g., chlorides and fluorides). Usually, the COD and BOD of pretreated gas condensates are decreased biologically. Aerobic microorganisms break down and metabolize most of the organics to carbon dioxide and produce sludge.

Essentially, two methods exist for *aerobic treatment* of gas condensates. The *activated-sludge process* is most common because it is less sensitive to variations in feed BOD. The *trickle bed process*, in which a film of microorganisms oxidizes the organics, is seldom used for gas condensates [262 – 264]. Sometimes PAC (powdered activated carbon) is used, mainly in activated sludge processes [265 – 269].

If the biotreated gas condensate is to be (partly) reused (e.g., as boiler feedwater), final filtration for removal of suspended solids and, if necessary, ion exchange (→ Ion Exchangers), reverse osmosis, or multiple flash evaporation for removal of strong anions may be employed as well.

Activated Sludge Process. For aftertreatment of gas condensates, a single stage consisting of an activated sludge basin equipped with aerators, to provide the required oxygen and effect mixing of the basin contents, and a clarifier for separation and thickening of the activated sludge is usually adequate. Nutrients (phosphorus and nitrogen compounds) for the microorganisms are needed in the ratio of BOD: N: P = 100: 5: 1. Gas condensates normally contain the required nitrogen in the form of fixed ammonia; phosphorus must usually be added in the form of phosphoric acid.

Typical design figures for biological aftertreatment of gas condensates to achieve a residual BOD_5 of 20 ppm are listed in the following material (MLSS = mixed liquor – suspended solids, water-free; BOD_5 = biological oxygen demand (five days); DO = dissolved oxygen).

Activated sludge basin:

Specific volumetric load, kg COD m^{-3} d^{-1}	ca. 1.00
Specific sludge load, kg BOD_5 kg^{-1} MLSS d^{-1}	ca. 0.25
Specific sludge content, kg MLSS/m^3	ca. 4.00
Oxygen content, ppm DO	1 – 2
Oxygen demand, kg O_2/kg BOD_5	ca. 1.50
Specific oxygen transfer, kg O_2 kW^{-1} h^{-1}	ca. 2.50

Postclarification basin:	
Retention time, h	ca. 2.50
Rise rate (water), $m^3\ m^{-2}\ h^{-1}$	ca. 0.80
Specific area load, kg MLSS $m^{-2}\ h^{-1}$	4 – 5

Addition of PAC to the activated sludge basin improves removal efficiency in some cases, because of various favorable properties of PAC: (1) substances toxic or inhibitory to biodegradation are adsorbed; (2) settling, thickening, and dewatering characteristics of the sludge are improved; and (3) the sludge age can be increased, resulting in higher retention times of difficultly biodegradable organics. Typical PAC consumption is 0.1 – 0.3 kg per cubic meter of gas condensate.

6.1.5. Removal of Heavy Metals

Wastewater from different processes (refining, coking, metallurgy, fossil fuel conversion, power generation, and others) contains greater or lesser amounts of heavy metals. The type and content depend mainly on feedstock composition [270, 271] and the conditions under which products come in contact with water (process condensates, quench water, cleaning liquid, etc.). Some of the wastewater must be treated for removal or recovery of heavy metals. Typical methods are liquid – liquid ion extraction, fixed-bed ion exchange, and precipitation by adding suitable chemicals such as metal salts, lye, or acid [272 – 274].

In the majority of all cases, gas condensates contain only small quantities of heavy metals. However, a considerable nickel and vanadium content is found, for instance, in gas condensates from partial oxidation of heavy fuel or vacuum residues. These metals are environmentally harmful. The new Lurgi Multi Purpose Gasification (MPG) process provides a special treatment of the heavy metals (MARS, Metals Ash Recovery System, see Sections 3.2.2 and 7.2). This reduces the metals concentration in the effluents considerably.

Precipitation of Vanadium and Nickel. After removal of hydrogen cyanide, carbon dioxide, hydrogen sulfide, and ammonia, the stripped condensate typically has a pH of ca. 6. It is cooled to 40 °C and fed to the heavy-metal removal plant, which consists mainly of precipitation steps, sludge dewatering and filter cake storage.

Precipitation of vanadium and nickel can be carried out in *one step* at pH 9 if all metals are to be removed in one mixture [273]. This mixture is clarified in a Sedimat (an automatic clarifier) [275], equipped with a central flocculation chamber to which a coagulant (polyelectrolyte) is added. The flocculated sludge settles to the thickening section in the bottom of the Sedimat, from which it is discharged.

The metal-free effluent is filtered to remove suspended solids, neutralized with sulfuric acid, and discharged to receiving water.

Thickened sludge streams from the clarifiers are filtered in order to reduce the water content to 70 %.

6.1.6. Example of an Industrial Application

Gas condensate from a typical Lurgi moving-bed coal pressure gasification with the following approximate composition, in grams per liter:

Tar (suspended portion only)	11.0
Oil (suspended portion only)	3.5
Suspended solids	1.5
Steam volatile phenols	4.6
Dihydric phenols	0.9
Fatty acids as acetic acid	0.7
Soluble organic substances	0.4
Free ammonia	15.6
Fixed ammonia	0.7
Carbon dioxide	32.0
Hydrogen sulfide	0.4
Free cyanide	0.1
Water	balance

and a flow rate of 500 m^3/h is to be treated so that 20 % can be released to receiving water, 75 % used as cooling tower make-up water, and 5 % used as boiler feedwater. A typical process sequence is shown in Figure 78. Intermediate battery limit conditions should be selected in such a way that total treatment cost is minimized whereas final conditions are still satisfied [276]. This leads to the following typical design criteria, in milligrams per liter, for intermediate product streams (after treatment):

Tar separation	
Total suspended matter	1000
CPI oil separators	
Total suspended matter	350

Dual media filters (for 500 m^3/h)	
Suspended matter	10
Phenosolvan plant	
Steam volatile phenols	10
Dihydric phenols	280
Ammonia recovery	
Free ammonia	50
Hydrogen sulfide	1
Activated sludge treatment	
BOD_5 reduction	from 700 to 20
Final dual media filtration	
Activated sludge content	20
Activated carbon posttreatment (using GAC, Granular Activated Carbon; [277])	
(for 400 m^3/h) Biologically refractory substance	5
Ion exchanger (for 25 m^3/h)	
Strong ions	10

In addition, the aqueous condensate treatment units will produce the following valuable byproducts, in tons per hour:

Tar	5.4
Oil	1.7
Crude phenol	2.7
Sulfur (via Claus plant)	0.1
Clean liquid ammonia	7.9

6.2. Hydrocarbon Condensates

The yield and composition of hydrocarbon condensates depend very strongly on the type of coal and the gasification conditions. In a countercurrent gasification system (e.g., Lurgi pressure gasification), coal travels through a retorting zone where volatile components are vaporized and leave the gasifier along with the gas. When the product gas is cooled in subsequent heat exchangers and coolers, different condensate fractions are recovered. When the temperature drops below the dew point of water, water condenses along with the hydrocarbons and forms an aqueous phase in the final separators (see Section 6.1).

Two fractions are recovered from Lurgi pressure gasification: a *tar fraction* containing the high boilers and an *oil fraction* boiling in the medium range. A third *light naphtha fraction* is obtained when the gas stream is cooled further for low-temperature purification in a Rectisol plant.

Figure 78. Treatment of aqueous condensates from moving bed coal gasifier (example given in the text)
* These processes are optional

Whereas the naphtha fraction can be treated directly in downstream units, the tar and oil fractions must be pretreated by conventional methods to remove suspended solid material (ash) and undissolved water. Typical properties and compositions of tar and oil are shown in Table 36.

To obtain products with suitable properties for use as fuel oil and gasoline, the combined pretreated medium- and high-boiling condensates are separated into their respective fractions by distillation [278]. Distillate boiling in the gasoline range is then refined along with the light naphtha fraction by hydrogenation to remove unsaturated compounds (which are potential gum formers) and to eliminate sulfur and ni-

trogen. Recovery of chemically pure compounds such as naphthalene or cresols (isomeric mixture) is usually uneconomic because of the small amounts present in the condensates [279].

Table 36. Typical composition of condensates from Lurgi pressure gasification

	Tar	Oil
Rate, wt % of total	60	40
Total water, wt %	10 – 15	15 – 20
Suspended solids, wt %	15 – 25	
Properties after removal of solids and undissolved water		
Specific gravity, d_{30}	1.05 – 1.1	0.94 – 0.96
Solidification temperature, °C	+ 15	< − 20
Flash point, °C	+ 60	+ 19
Water, wt %	4	2
Nitrogen, wt %	1	1
Sulfur, wt %	0.4	0.4
C_6– C_9 aromatics, wt %	6	16
Naphthalene, wt %	3	5
Methylnaphthalene, wt %	3	4
Phenolic compounds as cresol, wt %	21	19
Initial boiling point, °C	98	96
Portion distilled at 360 °C, wt %	60	75
Distillation residue, wt %	40	25
Properties of distillation residue		
Softening point, °C	67	63
Portion insoluble in toluene, wt %	10	7
Portion insoluble in quinoline, wt %	2	0.1
Coke (Conradson coking test), wt %	29	28

6.2.1. Distillation

In a first dewatering column, the water content is lowered by distillation. The dehydrated hydrocarbon condensate is then distilled in an atmospheric column. A typical distillation unit yields six fractions (see Table 37). Light and heavy naphtha are obtained as top and first side fractions; they are combined with the Rectisol naphtha and refined in a hydrogenation unit (see Table 38).

Two more side fractions, heavy and medium creosote, are recovered from the atmospheric column. The bottoms fraction is flashed into a drum under vacuum where it separates into vaporous residue oil and pitch.

Fractions boiling above 210 °C are used (e.g., as fuel or impregnation oil for wood). Pitch is suitable as a binder for briquetting of fine coal or may be fed to a partial oxidation plant to produce synthesis gas.

Table 37. Typical fractions from a coal tar distillation unit

	Approximate total, wt %	Approximate boiling range, °C
Light naphtha	4	≤170
Heavy naphtha	7	160 – 210
Medium creosote	25	190 – 290
Heavy creosote	21	260 – 400
Residual oil	13	max. 5 vol % ≤300
Pitch *	30	max. 15 vol % ≤350

* Softening point of pitch is ca. 70 °C; nonvolatile residue of pitch, max. 30 wt %.

Table 38. Typical feedstocks for hydrorefining (approximate figures)

	Heavy naphtha	Light naphtha from tar distillation	Light naphtha from Rectisol unit	Total blend
Rate, wt % of total	15	25	65	100
Specific gravity, d_{20}	0.93	0.84	0.83	0.85

Mercaptans, mg/kg	20	70	80	68
Phenolic oil, vol %	25			10
Alkaline nitrogen, mg/kg	10 100	7600	270	5000
Naphthalene, wt %	10			1.5
Initial boiling point, °C	130 – 140	90 – 95	50 – 55	55
Boiling end point at 95 wt %, °C	200 – 210	150 – 160	140 – 145	220
Chemical hydrogen consumption, m^3 (STP)/t	360	135	60	120

6.2.2. Hydrorefining

Hydrorefining is used (1) to saturate olefins and diolefins to their respective alkanes; (2) to convert sulfur in mercaptans and thiophenes to hydrogen sulfide; (3) to convert nitrogen in pyridines and amines to ammonia; (4) to convert organic chlorine to hydrogen chloride; and (5) to convert oxygen in phenols to water. The feedstock is a blend of the various naphtha streams recovered from condensates (see Table 38).

The *Benzoraffin process*, developed around 1960 jointly by BASF, Veba-Chemie, and Lurgi [280, 281], is commercially successful in refining the pretreated naphtha fractions derived from coal gasification. It is a fixed-bed, catalytic, gas-phase hydrogenation process using a cobalt – molybdenum catalyst operating at ca. 5 MPa and 350 – 420 °C (Fig. 79).

Figure 79. Benzoraffin process for hydrorefining of naphtha fractions
a) Feed pump; b) Vaporizer; c) Mixer; d) Prereactor; e) Heat exchanger; f) Reactor; g) Cooler; h) Separator; i) Recycle compressor

Modern alternatives to this process (e.g., by BASF, Lurgi-Südchemie, IFP et al.) — also used for the preparation of feedstocks for extractive distillation of toluene (→ Toluene, Chap. 3.1) — also work with two reactors, but the first reactor contains a palladium catalyst and operates in the liquid phase at low temperatures, preventing gum formation from diolefins or styrene.

The feed naphtha contains highly reactive chemical compounds with a strong tendency to form resinous deposits in heaters and vaporizers. A special vaporizer developed by Lurgi avoids fouling and frequent shutdowns for cleaning.

Process Description. Feed naphtha is vaporized under pressure and mixed with hydrogen-rich gas in a specially designed vaporizer (b) [281]. A small stream is withdrawn as residue from the bottom and returned to the tar distillation unit. The mixture of gas and naphtha vapor passes through a prereactor (d) filled with cobalt – molybdenum catalyst. Here, the most reactive unsaturated compounds are hydrogenated to prevent fouling in the heat exchanger (e). Reaction occurs at 200 – 250 °C. The outlet temperature is ca. 5 – 10 °C higher due to the exothermic reaction. After further heating in the heat exchanger (e) to about 350 °C, the prereactor effluent enters the main reactor (f). This reactor has two catalyst beds and a facility for injecting recycle gas to adjust the reaction temperature. The first bed contains cobalt – molybdenum catalyst pellets; the second bed is filled with a molybdenum catalyst. The exothermic reaction leads to an effluent temperature > 400 °C. The gas – vapor mixture is cooled to 30 – 40 °C in a heat exchanger (e) and cooler (g). Water should be injected into the cooler to prevent salt deposits, because hydrogen chloride and ammonia formed

during the reaction tend to solidify at lower temperature in the form of ammonium chloride.

The condensed raffinate is separated from the gas in a separator (h). After depressurization to ca. 1 MPa, the raffinate is stripped in a stripper column to remove hydrogen sulfide, ammonia, carbon dioxide, and water. If it still contains some phenolic compounds, a caustic wash and a subsequent water wash are recommended. A portion of the separated gas is withdrawn to remove sufficient light byproducts and inerts for the partial pressure of hydrogen to be adjusted properly. The main stream is compressed and recycled to the vaporizer after addition of fresh hydrogen.

A typical specification for a hydroraffinate from the naphtha blend in Table 38 is shown below.

Appearance	clear and free of suspended solids
Color, Saybolt	0
Water	max. 0.1 wt %
Total sulfur	max. 0.1 wt %
Existent gum	max. 4 mg per 100 mL
Aromatics	ca. 75 wt %

Because of its high aromatic content, this raffinate is a valuable blending component for gasoline. Alternatively, pure benzene, toluene, and other aromatics may be recovered from the raffinate by appropriate separation processes. Solvents with specified boiling ranges for various applications in the chemical industry can be obtained by fractionation.

6.3. Gaseous Byproducts

Sulfur Compounds (→ Hydrogen Sulfide, see → Sulfur). Hydrogen sulfide constitutes the main part of the gaseous sulfur components. It usually accounts for 90 – 95 % of the sum of all sulfur compounds. The remainder is primarily COS; CS_2, SO_2 and mercaptans are usually present in trace amounts only.

These sulfur components occur in various waste gases and are more or less strongly diluted with CO_2. Hence, processing depends totally on their concentration and usually aims at recovering elemental sulfur. In special cases, the direct production of sulfuric acid can also be of interest and even low concentrated H_2S gases can be used for this purpose.

There are various methods available for the recovery of elemental sulfur from low concentrated waste gases (e.g., 1 % H_2S, 98 % CO_2 and 1 % inert gases). These methods include concentration by selective absorption or by adsorption, and sometimes intermediate steps with (partial) combustion to SO_2 are also involved. Processes of this type have been occasionally employed.

From a theoretical standpoint, the most economical method should be direct oxidation, either in the gaseous or in the liquid phase as performed in an oxidation wash, e.g., the Lo-Cat process (see Section 5.4.3). However, it should be taken into consideration that organic sulfur compounds in the gas, primarily COS and CS_2, remain practically unchanged and this could represent an undue environmental burden. On the other hand, precautionary measures must be taken if the waste gas contains trace components, such as HCN, that could cause solvent degradation. Therefore, low investment cost are often counterbalanced by high operating cost for solvent reclaiming and/or make-up of chemicals. Today oxidation wash systems are mainly used for low-pressure off-gases with low sulfur contents, with limitations in capacity.

If hydrogen sulfide is present in concentrated form, i.e., in concentrations of more than 20 % (in some cases 10 % are sufficient) sulfur can be recovered more economically by using the Claus process. However, the Claus tail gas almost always requires an additional treating step; it usually still contains 3 to 6 % of the sulfur, mainly in the form of H_2S and SO_2. A modern solution is the integration of a three stage Doxosulfreen process (→ Sulfur, Chap. 7.2.1.1) shown schematically in Figure 80. Here, the first two catalytic reactors after the combustion chamber are continuously operated according to the classical Claus principle. After condensing the elemental sulfur formed in the Claus reactors, COS and CS_2 are converted by catalytic hydrolysis at elevated temperature. The following reactors — each containing a Sulfreen stage and a direct oxidation stage — are operated in cycles: in one, the Claus reaction is first, at a slight surplus of H_2S, continued below the sulfur dew point with adsorption of the newly formed sulfur, and then, at further reduced temperature, the residual H_2S is almost completely converted by catalytic oxidation with air. In the second reactor, operated

Figure 80. Two-stage Claus plant with internal hot gas bypass, integrated Doxosulfreen plant and thermal incineration
a) Claus reactors; b) Sulfur condensers; c) Separators; d) Heater; e) Hydrolysis reactor; f) Cooler; g) Sulfreen and h) Direct oxidation stages; i) Thermal incineration

in parallel, the sulfur is desorbed by acid recycle gas and is subsequently, as in the first two steps, separated in liquid form in coolers, with the generation of LP steam [282].

Carbon Dioxide. Today, there are basically four different ways of releasing sulfur-free carbon dioxide:

- Release into the atmosphere (there might be restrictions in the future),
- Use for enhanced oil recovery (EOR) or
- As chemical raw material, and
- Recovery as pure CO_2 for the food and pharmaceutical industry.

Usually a large part of the CO_2 waste gas is released into the atmosphere for lack of other uses, although it should be taken into consideration that even sulfur-free CO_2, in larger concentrations, is dangerous (in Germany the MAK value is 5000 ppm). However, in the case of furnaces, a sufficiently high flue-gas temperature normally ensures adequate dilution in the atmosphere; special precautions are required for cold process waste gases and the high carbon dioxide density relative to air. If introduction into a flue gas is not possible (dew point!), cooling towers can be used provided that the danger of corrosion is taken into account, otherwise, only special stacks may be employed.

In connection with the general discussion about the various factors influencing the earth's climate and the necessity to decrease the CO_2 emission into the atmosphere, several solutions have been considered theoretically, e.g., the depositing of CO_2 in absorbed form in deep layers of the oceans. However, none of these suggestions have been realized so far on a technical scale.

One of the more modern applications of CO_2 is in enhanced oil recovery. The specification for the CO_2 to be injected in aging oil wells (to reduce the oil's viscosity) is usually less stringent: CO_2 concentration 98 %, C_1/C_{3+} hydrocarbons up to 0.3 %, total sulfur in the 1 % range. This purity may often be accomplished simply by dehydration of the raw CO_2 [283].

Various requirements have to be met for the use of carbon dioxide as a *chemical raw material*: in the production of carbon monoxide or synthesis gas from natural gas, which has the lowest C/H ratio of all raw materials, carbon dioxide is frequently removed from the process gas by absorption and recycled to the reformer. Care must be taken that the catalyst used is not

damaged by solvent vapors or other trace components. Waste gases from hot potash, amine, and physical washes operated with sulfur-free solvents generally cause no problems, as long as effective separators are employed which are usually followed by a re-compression step. This compression step also contributes to residual separation.

Carbon dioxide used in the *synthesis of urea* has to meet more stringent requirements. Indeed, a maximum concentration of inert gases, usually 1 – 2 % of hydrogen and carbon monoxide, should not be exceeded and sometimes even traces of solvents can cause problems. However, these small amounts can generally be separated by a simple adsorption step with an appropriate molecular sieve.

The highest demands are made on the purity of carbon dioxide used in the *pharmaceutical* or *food industry*, e.g., in the form of dry ice for cooling or packaging purposes or in compressed or liquid form for the production of beverages. Depending on the impurities to be separated (even a few ppm of odorous substances are often sufficient to cause an unpleasant smell), usually several different, usually adsorptive, purification steps are necessary. More modern installations include also distillation stages (to separate "sour CO_2" together with heavier hydrocarbons and light inerts) as well as oxidation stages to convert the reminder of undesirable hydrocarbons (Fig. 81) [283, 284].

7. Typical Examples of Complex Gas Production Plants

7.1. Methanol Production from Natural Gas

The production of methanol (→ Methanol) with natural gas (→ Natural Gas) as feedstock is described by the following process steps: (1) gas production, (2) methanol synthesis, and (3) distillation. Details of the three single process steps are described in other chapters; this chapter deals with specific features of the overall arrangement.

Basically two different gas production technologies, steam reforming and catalytic autothermal reforming, or a combination of both are used to produce methanol from natural gas, depending on plant size and availability of carbon dioxide from outside battery limits.

Synthesis gas produced by *steam reforming* is characterized by a relatively low pressure and a surplus of hydrogen. By addition of carbon dioxide the composition of the synthesis gas can be adjusted to be more favorable for methanol production.

Pure catalytic *autothermal reforming* results in a synthesis gas with a relatively high pressure but with a deficiency in hydrogen for methanol synthesis. A carbon dioxide removal unit is required or additional hydrogen has to be provided to adjust the appropriate gas composition. Such hydrogen may be obtained either from the methanol synthesis purge gas and from additionally produced reformed gas or from a conditioned methanol synthesis purge gas.

The combination of both technologies, the so-called *combined reforming process*, has the advantage of an optimum composition and a high pressure of the produced synthesis gas.

For the methanol synthesis itself a wide range of technologies are available, which differ mainly in the design of the methanol converter. In principle, three different types of converters are used in the industry; the quench-cooled, the gas-cooled, and the water-cooled reactor. For optimization of the reaction and for capacity increase also combinations of these technologies are applied.

In the distillation section the raw methanol produced in the synthesis section is purified to meet the required specification. Depending on plant capacity and optimization with regard to cost or energy savings, a two or three column concept can be used.

At locations where no carbon dioxide is available most of the methanol plants are based on the following gas production technologies, depending on their capacities: steam reforming for capacities up to 2000 t/d, combined reforming from 1800 to 2500 t/d [285, 286].

Erection of plants with a capacity of 5000 or even 10 000 t/d is also discussed nowadays, e.g., for minimizing flaring of associated gas in oil fields by producing methanol as a "liquid storage". For this size of plants pure catalytic autothermal reforming in combination with a high efficient conversion of synthesis gas to methanol is the most economical way. The process is

Figure 81. Purification of CO_2 for the production of beverages
a) Fractionation; b) Adsorptive sulfur guard; c) Catalytic oxidation; d) Adsorptive dryers

designed in such a way that conditioned purge gas with the required hydrogen content is obtained to adjust the reformed gas composition. This technology is illustrated in the simplified process flow diagram in Figures 82 and 83 and described in Section 7.1.1.

Steam reforming technology and combined reforming technology are discussed in Section 7.1.2.

7.1.1. Methanol Production Based on Catalytic Autothermal Reforming (Figs. 82 and 83)

Gas production, methanol synthesis, and subsequent distillation are the primary process steps. The relevant units are combined with an integrated steam system usually on several pressure levels. Steam is generated and conditioned in the synthesis, in the reformed gas and flue gas waste-heat system, and in the auxiliary boiler.

Natural gas is preheated and desulfurized. After desulfurization the gas is saturated with a mixture of preheated process water from the distillation section, process condensate, and make-up water in the saturator (d). The gas is further preheated and mixed with process steam as required for the prereforming process. In the prereformer (f) the gas is converted to hydrogen, carbon dioxide, and methane. Final preheating of the gas is achieved in the fired heater (b). In the autothermal reactor (g) the gas is reformed with steam and oxygen, the product gas contains hydrogen, carbon monoxide, carbon dioxide, and a very small amount of non-converted methane and inerts together with undecomposed steam. The reformed gas leaving the autothermal reactor possesses a considerable amount of heat, which is recovered in form of high pressure steam, preheating energy, and energy for providing heat for the reboilers in the distillation section.

The reformed gas is mixed with hydrogen from the pressure swing adsorption unit to adjust the synthesis gas composition. Synthesis gas is pressurized to 5 – 10 MPa by the synthesis gas compressor (o). Subsequently, this compressed gas is mixed with recycle gas from the synthesis loop. With the recycle gas compressor (t), the recycle: make-up gas ratio can be adjusted. The inlet gas to the reactor system consists mainly of hydrogen, carbon monoxide, and carbon dioxide as reactive components, along with methane and nitrogen as inerts. This gas mixture is converted to methanol according to the following exothermic reactions:

$$CO + 2\,H_2 \rightleftharpoons CH_3OH$$

$$CO_2 + 3\,H_2 \rightleftharpoons CH_3OH + H_2O$$

Details of the reaction mechanism are described elsewhere (→ Methanol). The synthesis reactor system (q) is the key section of the loop. Here superheating of the catalyst is avoided by generation of medium pressure steam and the reaction parameters are selected in such a way that properly conditioned purge gas is obtained.

In the pressure swing adsorption unit hydrogen is separated from the purge gas and routed to the reformed gas. The remaining gas is used as fuel in the fired heater.

The distillation unit is a three-column energy-saving system. In the light-ends column (u), low-boiling impurities are removed overhead.

Pure methanol distillation is divided into two sections. The first section (v) operates at elevated pressure, and ca. 50 % of the methanol is distilled overhead. In the second section (w), which operates at ambient pressure, the remaining methanol is separated from water and high-boiling impurities.

Whereas the first section is heated with low-pressure steam, heat for the second section is provided by condensing methanol vapor from the first section.

7.1.2. Comparison of Conventional Steam Reforming and Combined Reforming Processes for Methanol Production

The main reason for applying the combined reforming process in methanol production is adjustment of the stoichiometric number (SN) as defined in Table 39, closer to the theoretical value of 2.0. Whereas the practical SN is between 2.6 and 2.9 for conventional steam reforming, it is decreased to 2.03 in the combined reforming process.

Table 39. Conventional steam reforming versus combined process for methanol production

	Conventional steam reforming	Combined process
Process natural gas feed to tubular reformer, %	100	40 – 60
Process natural gas feed to autothermal reactor, %		60 – 40
Outlet pressure tubular reformer, MPa	1.9	3.7
Outlet pressure autothermal reactor, MPa		3.5
Outlet temperature tubular reformer, °C	875	780
Outlet temperature autothermal reactor, °C		950
Hydrocarbons converted in tubular reformer, %	83	22
Stoichiometric number, SN = $(C_{H_2} - C_{CO_2}) / (C_{CO} + C_{CO_2})$	2.6 – 2.9	2.03
Total natural gas lower heating value demand, GJ *	31.6	29.5
Thereof fuel consumption of reformer, GJ *	12.9	3.1

Besides reducing the SN, placement of an autothermal reactor downstream of the tubular reformer means that the tubular reformer can be drastically reduced in size for two reasons: first, it has to treat only about half of the natural gas feed while the other half is by-passed directly to the autothermal reactor and, second, it does not have to convert all of the methane but leaves an essential part for the secondary reforming step. So the fired steam reformer may be ca. 75 % smaller, can operate at lower temperature, and therefore, can operate at higher pressure than a steam reformer in the conventional steam reforming process.

Because of the lower SN, less surplus hydrogen must be compressed and introduced into the synthesis loop, which results in a significant reduction of equipment size and compression energy. Table 39 shows the main operating data of the combined reforming process in comparison with the conventional steam reforming process.

7.2. Hydrogen Production Based on Heavy Residues

Economic and environmental considerations have led petroleum refiners to intensify efforts to maximize production of high-quality products from crude oil. To meet this goal, a number of refinery processes have been developed to upgrade heavy residues to, for instance, naphtha and gas oil. Some of these conversion processes (e.g., hydrotreating or hydrocracking) require considerable quantities of hydrogen. Today most of the hydrogen is produced by steam reforming of natural gas (83 % of total production) or naphtha (14 %). Only 3 % is obtained by gasification of heavy residues [287]. However, though the capital investment for such a plant is considerably higher than for a unit based on steam reforming of natural or refinery gas, gasification of residues can still be advantageous, particularly where natural gas or other light hydrocarbons are not readily available or expensive.

In some refining schemes, particularly those for treating heavy crudes, the hydrogen balance of the refinery may require utilization of the residues for hydrogen production. In addition, partial oxidation of heavy residues can contribute to reducing the size of the fuel oil pool

and increasing its quality by consuming some of the highest sulfur- and metal-containing components of the pool [288].

A typical hydrogen specification for a hydrocracker is

Hydrogen	$\geq$98 %
Carbon monoxide and carbon dioxide	$\leq$10 – 50 ppm
Oxygen	$\leq$100 ppm
Inerts (N_2, Ar, CH_4)	balance

The raw gas supplied by a partial oxidation unit fed with a heavy residue contains nearly 50 % carbon monoxide, as well as other components (CO_2, H_2S, COS) which must be converted or removed in a number of gas treatment stages to yield acceptable product quality (see Table 24, example 3). In practice, gas plants based on partial oxidation are often multiproduct plants, which in the refinery environment could imply cogeneration of clean fuel gas or, for example, methanol for methyl-*tert*-butyl ether (MTBE) (→ Methyl Tert-Butyl Ether) production.

Selection of gas treating processes must be made carefully, because ca. 20 – 30 % of the total investment for an overall hydrogen plant is concentrated in these units. Plant size and possible cogeneration of other products also influence the final choice of process.

For the partial oxidation unit, either of the three commercially proven processes (Shell, Texaco, Lurgi) is suitable.

Conventional Gasification-Based Hydrogen Production. The principal process steps for hydrogen production based on heavy residues as feedstock are as follows (see Figure 55):

- Gasification
- Acid gas removal (H_2S, CO_2), in one or two separate units
- CO shift conversion
- Final purification

The byproducts have to be handled within the refinery (steam, fuel gas) with the appropriate specifications or should be salable (sulfur, metal ash).

As outlined in Section 3.2.2, the gasification process itself can be applied in two different configurations followed by different downstream treatment modes of the raw synthesis gas:

1) Gasification in *boiler configuration* with downstream CO shift of desulfurized syngas.
2) Gasification in *quench configuration* with raw gas shift (see Section 5.1) prior to desulfurization (and CO_2 removal).

In the *boiler configuration*, the sensible heat of the hot raw gas leaving the gasification reactor is utilized to generate high-pressure steam in a waste-heat boiler before the gas enters the scrubber. After the subsequent desulfurization and a clean gas CO shift conversion, CO_2 must be removed from the syngas by a second washing step. This route has been chosen for the Shell Pernis plant [289]. The disadvantages of this concept are high capital costs due to the expensive gasification stage (waste-heat boiler), CO shift conversion (with cooler-saturator circuit) and the two-stage acid gas removal unit along with limited feedstock flexibility due to the boiler specification. An asset is a rather high thermal efficiency.

In the *quench configuration*, the raw gas leaving the gasifier is shock-cooled by direct injection and subsequent scrubbing with water. It can thus be routed directly to the sulfided CO shift conversion (raw gas shift). The steam content of the quenched gas is normally sufficient for the shift reaction, which leads to a quite simple layout of the shift conversion plant. Furthermore, trace components like COS and HCN are destroyed in the shift reactor, which facilitates the subsequent acid gas removal. This concept has been proposed by Texaco [290] and Lurgi [291, 292]. The advantage of this concept is lower capital cost for both the gasification unit and the shift. A disadvantage is the loss in thermal efficiency.

Improved Route for Hydrogen Production. In order to further increase the economics of a gasification-based hydrogen production unit compared to a further steam reforming step, the above described quench configuration route has been improved by Lurgi introducing the Multi Purpose Gasification together with an advanced ash handling system and an optimized CO shift conversion. The new concept consists of the following process units (Fig. 84):

- Air separation and oxygen compression,
- Multi Purpose Gasification (MPG) in quench configuration,
- Metals Ash Recovery System (MARS),
- Sulfided CO-Shift (single-stage raw gas shift),
- Sulfur removal (Rectisol process),
- Pressure swing adsorption (for remaining CO_2 and low concentrated impurities),

Figure 84. Block flow diagram of the MPG based hydrogen production
ASU = Air separation unit; MPG = Multi Purpose Gasification; MARS = Metals Ash Recovery System; PSA = Pressure swing adsorption; SDA = Solvent deasphalting; BFW = Boiler feed water; CW = Cooling water

– Sulfur recovery unit (Claus process).

Two main features make this concept most economic compared to conventional process routes:

1) The MPG process with its high feedstock flexibility allows the simultaneous processing of even the heaviest refinery residues and wastes, which can reduce the costs for feedstock supply (see below).
2) In the sulfided CO shift, the raw gas is converted in a single-stage reactor which results in an increased CO content in the converted gas. On the one hand, this leads to a lower H_2 yield and therefore requires more feedstock to be processed in gasification. The advantages, however, are:
   – A self-burning PSA off-gas which can directly be used as fuel gas in an auxiliary boiler or sent to the refinery's fuel gas system. There is no need for fuel import.
   – The capital costs for the overall plant are reduced because of the cheaper CO shift conversion and the cheaper CO_2 removal.

A simplified process flow diagram of the gasification and shift conversion section is shown in Figure 85. The raw gas is produced by partial oxidation of heavy residues using Lurgi's Multi Purpose Gasification Process in quench configuration at 6.0 MPa. The water-saturated raw gas from the quench vessel enters the scrubber at ca. 240 °C, where residual soot/ash traces are removed by injection of additional quench water. No further raw gas cooling occurs in the scrubber. The water leaving the quench section contains most of the soot and ash from the raw gas and is further treated in the Metals Ash Recovery System (see Section 3.2).

The raw gas from the MPG unit is saturated with water and routed to the CO shift conversion unit. After preheating of the raw gas, its CO content is reduced in a single-stage reactor to a residual 6 to 9 %, depending on the composition of the feedstock. No further steam injection into the shift feed is necessary to maintain the shift reaction. The sensible heat of the shifted gas is recovered by producing steam of different pressure levels and by preheating several water streams (quench water, demineralized water). The con-

Figure 85. Simplified process flow diagram for the gasification (quench configuration) and the CO shift section in Figure 84

densate from the cooled shift product gas is sent to the MPG unit as quench and scrubbing water.

Both carbonyl and hydrogen sulfides are washed out of the gas to a residual 1 ppm in a *one—stage Rectisol unit*. The factors determining the selection of the Rectisol process instead of a chemical absorption system are

- Low steam consumption,
- High selectivity for H_2S versus CO_2 for the generation of a rich acid gas to facilitate the sulfur recovery.(see 5.4.2.4) for detailed discussion on acid-gas removal options).

The acid gas, which contains 25 – 60 % hydrogen sulfide, depending on the sulfur content of the feedstock, is normally discharged to a central Claus plant that also treats other sulfur containing gas streams originating in the refinery to produce elemental sulfur.

In the *final purification* of the raw hydrogen in the pressure-swing adsorption unit CO_2 and other impurities are reduced to 10 ppm of carbon dioxide, 10 ppm of carbon monoxide, and 0.1 % (maximum) of inerts, yielding hydrogen with a purity > 99.9 % (see Section 5.5) at a pressure between 4.7 and 4.8 MPa.

Plant Performance. For easier comparison of the improved concept with conventional process routes, three cases are considered for the economic evaluation:

Case 1: = MPG (quench) + single-stage raw gas shift + H_2S absorption + PSA

Case 2: = MPG (quench) + two-stage raw gas shift + acid gas absorption (H_2S, CO_2) + PSA (for remaining impurities only)

Case 3: = Texaco Gasification (TGP, quench) + two-stage raw gas shift + acid gas absorption (H_2S, CO_2) + PSA (based on [290], scaled to hydrogen production without power generation)

The characteristics of the respective plant performance are summarized in Table 40.

To compensate for the lower H_2 yield of the MPG/single-stage CO shift process variant, the plant capacity must be by 6 % higher which leads to higher variable operating costs. On the other hand the simple plant configuration of this route results in lower capital costs and fewer maintenance costs and therefore reduced fixed costs which makes this concept the most economical one.

7.3. Combined Cycle Power System Based on Coal

7.3.1. Introduction

Combined cycle power plants are an attractive option to raise the efficiency of electric power generation. This power plant concept combines a gas turbine and a conventional steam turbine

Table 40. Performance of improved-concept plants for hydrogen production from heavy residue

cycle. Based on available industrial gas turbines early plant concepts were developed and introduced in the early 1950s, these plants were fueled by conventional oil-derived gas or almost any kind of fuel gas. Although basic process concepts are well established, novel concept variations are still under development [293].

Due to its relatively low price as well as regional availability, coal is the major fuel for fossil-fueled power plants. To use combined cycle technology, coal must be transformed into a clean fuel applicable to gas turbine operation (the same applies to residual oil, petroleum coke, or wood). Impurities, which must be removed, are ash, alkali, halogens, and sulfur. Typical gas turbine specifications are given below:

Inlet temperature, °C (according to ISO)	1190
Na + K, mg/kg	0.08
V, mg/kg	0.1
Pb, mg/kg	0.25
C, mg/kg	2.5
Cl, mg/kg	2.45
Dust < 2 µm, mg/kg	4.4

The only way to meet these requirements is gasification because

1) Ash remains in the gasification residue,
2) Alkali is trapped within the ash or removed in one of the purification steps, and
3) Halogens and sulfur are removed by dry or wet absorption.

The combined effect of high efficiency and low pollution makes the combined cycle with upstream coal gasification an attractive approach for power generation from coal. In principle, two designs are possible: integrated and nonintegrated plants. In the latter, the gasification and gas purification process units are installed and operated separately from the power plant. This makes power plant operation easier, but an integrated plant (IGCC) allows for more sophisticated energy management and higher efficiency [294]. Hence, most engineering and economic studies and first-of-its-kind plants refer to this design principle. In this section only the principles of the integrated combined cycle based on the gasification of solid fuels are discussed [295, 296].

Environmental Aspects. The emissions of combined power cycles are inherently lower than that of coal combustion plants [297 – 299]. This is due mainly to the following characteristics:

1) Desulfurization of the fuel gas can be accomplished to any extent necessary at a relatively low additional cost. For applicable processes, see Section 5.4.
2) The byproduct of desulfurization is elemental sulfur, which can be sold or easily disposed of, in contrast to flue gas scrubber residues.
3) Low NO_x emissions are achievable due to the tightly controllable combustion conditions in a gas turbine.
4) Extensive particulate removal is essential for gas turbine operation, resulting in dust emissions far below existing requirements.

7.3.2. Fundamentals

Thermodynamics [300, 301]. Electric power is conventionally generated by combustion to produce high-temperature thermal

energy and converting that thermal energy into work to drive a generator. The working fluid can be the combustion gas itself or a special working medium (steam, air) to which heat is transferred from the combustion gas.

The upper limit to the proportion of thermal energy converted to work is set by Carnot's law

$$\eta \approx 1 - \frac{t_2}{t_1}$$

where t_1 and t_2 are the upper and the lower absolute temperatures of the working fluid and η is the conversion efficiency. For a *steam turbine cycle* construction materials usually limit the upper temperature to ca. 560 °C, the lower temperature depends on the available cooling water temperature. With sea water cooling lower temperatures of ca. 30 °C are achievable. For an open cycle *gas turbine* (stationary application), t_1 may be as high as 1050 °C, with t_2 being ca. 500 °C depending on the pressure ratio.

When gas and steam turbines are combined by using the thermal energy of the gas turbine exhaust gas to produce and superheat the steam from the steam cycle, t_1 may be as high as 1050 °C and t_2 as low as 30 °C. This, in simplified terms, is the basis for the efficiency increase when a *dual cycle* combining gas and steam turbines is used instead of a *single* working fluid cycle. Some losses occur along the route from coal to electrical energy. For simplification the overall efficiency of the process can be written as the product of individual efficiencies:

$$\eta = \eta_{CG} \cdot \eta_{GC} \cdot \eta_{CC}$$

where η_{CG} is the efficiency of coal gasification; η_{GC}, the efficiency of gas cleaning; and η_{CC}, the efficiency of the combined cycle.

Efficiency of Coal Gasification η_{CG}. Coal gasification processes suffer losses of useful energy due to the following mechanisms:

1) The heat of evaporation of gasification steam, coal moisture or slurry water cannot be recovered.
2) The bottom or fly ash inevitably contains unconverted carbon which is lost for the process. The same applies for the sensible heat of the ash.
3) Heat is lost to the environment, e.g., through the walls of apparatus and pipes.
4) The operation of drives, pumps and compressors consumes electric energy, which can be recovered only partly.
5) The gasification reactions require elevated temperatures. During cleaning of the hot raw gases, according to the requirements of the gas turbine operation and of the environment, the raw gas has to be cooled down by heat exchange which involves a certain degree of irreversibility.

Each of the mechanisms leads to a different amount of losses for the individual gasification processes. Reference figures for η_{GC} may be taken from Section 4.4, 4.5, 4.6, 4.7 (Tables 18, 20, 21, 23).

Efficiency of Gas Cleaning η_{GC}. The losses of useful energy during gas cleaning can mainly be attributed to

1) Nonreversible heat exchange during cooling of the raw gas and reheating of the clean gas,
2) The energy required for the regeneration of the solvent or adsorbent, which in most instances is lost,
3) The removal of sulfuric components and the co-removal of other combustible constituents of the raw gas which, therefore, cannot contribute to the combined gas/steam turbine operation,
4) The removal of inerts such as H_2O and CO_2 which reduces the mass flow through the gas-turbine and hence its energy output, and
5) The consumption of electric energy.

In most cases η_{GC} reaches 96 – 98 %.

Efficiency of Combined Cycle η_{CC}. For thermodynamic reasons the efficiency of the conversion of thermal energy into work and consequently electric power is limited as has been explained earlier. In addition to that, other losses of useful energy must be considered, e.g.:

1) The heat of evaporation of boiler feed water is only partly used for generation of power.
2) The nonideal operation of gas and steam turbines increases the entropy of the working fluids.
3) The flue gases leave the stack with a temperature above 100 °C, their thermal energy is not used for the process.
4) Heat losses through the insulation.

Based on *natural gas*, a combined cycle with a gas turbine inlet temperature of 1100 °C (according to ISO) may reach 48 % efficiency [299, 302].

At a *coal gasification* efficiency of ca. 90 % a combined cycle power generation unit based on coal gasification achieves an overall efficiency $\eta > 42\,\%$.

General Plant Arrangement. In principle, any high-pressure coal gasification process mentioned in Chapter 4 can be used as the front-end process. The selection of a gasification process depends on several boundary conditions, the most important of which are

1) Type of available coal (rank, particle size, ash, and moisture content);
2) Gasifier efficiency; and
3) Maturity of the process and its proven reliability.

Coal gasification can be integrated with combined cycle power generation in numerous ways. Modifications differ in the degree of carbon conversion (partial or total gasification), the gasification medium (air or oxygen), the measures taken to adjust the turbine inlet temperature (excess air or steam production), and the general arrangement (stand-alone plant or repowering). Advantages and limitations of the individual variants are described in [294, 297], and [303 – 307].

7.3.3. Installations and Design Studies

Installations. The first commercial-scale IGCC plants have been built at Lünen by Steag in the Federal Republic of Germany [308] and near Barstow, California (The Cool Water plant). The Lünen plant with a design output of 170 MW operated between 1972 and 1977; the Cool Water plant (100 MW) began operation in 1984. At present both plants are no longer in operation.

Lünen IGC Plant. The general arrangement of the Lünen plant is shown in Figure 86. Gasification takes place in 4 + 1 Lurgi moving bed gasifiers (see Section 4.4). High volatile subbituminous coal is gasified with steam and air countercurrently at a pressure of 2 MPa (c). The raw gas leaves the gasifiers with a temperature of 500 – 600 °C. It is cleaned in a scrubbing unit (d) where dusty and tarry compounds are removed from the gas. Simultaneously the gas is cooled to ca. 160 – 170 °C and saturated with water. The dusty tar removed from the gas is recycled in total to the gasifiers after separation from the wash water. The clean gas is passed through a first gas turbine (e) which drives the booster compressor (b) for the gasification air. Here the pressure of the clean gas is reduced from 2 to ca. 1 MPa. A bypass stream of 1 % of the clean gas is desulfurized with a hot potassium wash solution for pilot test purposes.

Figure 86. Simplified flow diagram of the IGCC Lünen plant
a) Air compressor; b) Gasification air compressor; c) Lurgi gasifiers (in all five); d) Wet gas cleaning; e) Expansion turbine; f) Supercharged boilers (in all two); g) Gas turbine; h), i) Boiler feed water preheaters; j) Steam turbine; k) Condensor; l) Boiler feed water pump; m) Generator

The clean gas is combusted in two supercharged boilers (f) at 1 MPa which is a particular feature of this plant. In these boilers 340 t/h steam are generated (13 MPa, 525 °C) powering a steam turbine (j) with an output of 96 MW.

The flue gases leaving the supercharged boilers drive a second gas turbine (g) with an output of 74 MW. The compressor for the total plant air is connected to the same shaft. In the gas turbine the flue gas enthalpy is reduced from 1.0 Pa, 810 °C down to 0.1 MPa and 400 °C. The residual thermal energy of the exhaust gases is used for boiler feed water heating (i, k), the stack inlet temperature is 170 °C [297, 309].

As a first-of-its-kind plant, the Lünen plant did not operate continuously; altogether it produced electrical energy for the grid for ca. 10 000 h. During this time, the data in Table 41 were obtained.

Table 41. Performance data, in percent, of the Lünen plant at 70 % partial load

Efficiency	Partial load			100 % load
	Design	Operation		Design
	Design coal	Coal 1 *	Coal 2 **	Design coal
η_{CG}	91.7	90.2	86.1	92.9
η_{CC}	35.8	35.2	35.0	39.4
η	32.8	31.7	30.5	36.7

* Coal 1 = design.
** Coal 2 = low grade (40 % < 5 mm, 28 % ash).

The plant generally operated at partial load and with low-grade coal. Table 41 also shows estimated full load design data which were not achieved because only 70 % of the necessary gasification air could be supplied due to limitations in air compression.

The second commercial-scale installation is the Cool Water plant [310, 311]. The plant is of commercial size, with a net output of ca. 100 MW.

In this plant, a Texaco entrained-flow gasifier (see Section 4.6) was used, which gasified a coal – water slurry with oxygen. According to prevailing emission standards, the gasification raw gas was purified by a physical absorption process (Selexol, see Section 5.4), which reduces the content of carbonyl and hydrogen sulfide in the purified gas to 50 ppm. Besides demonstrating the IGCC process principles the Cool Water plant was used to test construction materials and general control strategies.

Design Studies. The two plants have not been designed to exploit the full potential of IGCC. Their main purpose was the demonstration of the technical feasibility and operability of plants of this kind.

Hence the overall efficiency of these early IGCC plants is limited compared to modern power stations based on the Rankine process.

The successful introduction of natural gas fired IGCC plants stimulated numerous design studies based on gasification of solid fuels. Gasification processes which were considered are the Lurgi fixed-bed gasification [297], the British Gas/Lurgi slagging gasifier [304, 312, 313], entrained-flow gasification [304, 305], and fluidized-bed gasification [305, 314 – 316]. Depending on constraints like available fuel quality and sophisticated heat recovery systems efficiencies $\eta \gg 40$ % can be expected.

The most recent commercial scale IGCC power plants based on coal gasification have been commissioned at Buggenum (NL) (250 MW) by DEMKOLEC B.V. [317 – 319], at Puertollano (Spain) (320 MW) [320]; and Tampa (USA) [322]. The DEMKOLEC Buggenum plant applies entrained-flow gasification for turbine fuel production; standard fuel is conventional hard coal (ca. 2000 t/d). Commercial operation started in 1994. In a single train 250 MW of electric power are generated; based on the experience gained so far, capacities of 500 MW are regarded as feasible. The block diagram (Fig. 87) depicts the main building blocks of a typical IGCC layout following the DEMCOLEC design; Figure 88 presents an aerial view of the total plant . A major part of the setup is taken up by the gas cleaning and desulfurization systems. A conventional Claus – SCOT plant converts H_2S to elemental sulfur. The IGCC plant at Puertollano uses an entrained-flow gasifier to convert low grade subbituminous coal into fuel gas for a gas turbine [320, 321]. This project is jointly executed by several companies of different European countries and funded by the European commission. The Tampa IGCC plant was commissioned in 1996, using entrained-flow gasification; in addition to hard coal refinery residues can be used for gasification [322].

Besides these plants in operation, numerous studies investigated the suitability of IGCC plants for a wide range of feedstocks [314, 316, 323]. IGCC concepts have also been investigated with regard to the gasification of unconventional fuels [319, 323 – 325]. The use of biomass de-

Figure 87. Principle layout of an IGCC plant

rived fuels opens the possibility for a reduction of CO_2 emissions whilst retaining high power generating efficiencies.

Figure 88. Aerial view of the DEMKOLEC plant

8. Analysis and Quality Control

Fuel gases [336] are sold principally as a source of energy, but in units described by volume. Consequently, considerable demand exists for specification of the thermal content per unit volume. The range of fuel gases that will burn satisfactorily on a particular appliance is limited and best described by the *Wobbe index* of the gas. The Wobbe index is a measure of the heat input to an appliance at constant pressure, and is expressed as the ratio of the calorific value to the square root of the relative density. This property should also be specified. *Safety requirements* relate to the flammable nature of the fuels, and engineering considerations relate to their distribution and storage.

Specifications for fuel gases cover various properties and may be devised or imposed by different authorities. Requirements for the specification of and means of ensuring *satisfactory odorization* are commonly a responsibility of government. Control of Wobbe index and of particular components that may have operational implications, such as water and condensable hydrocarbons, are usually the responsibility of the supply and distribution company. Different countries have different specifications [337], although common interests ensure a degree of consistency.

If a fuel gas is to be used as a *chemical feedstock*, quite different specifications will be used; total carbon content and the quantity and types of sulfur compounds present might be of much greater importance.

8.1. Quality Specifications

Natural gas supplies by far the greater part of the fuel gas market. The quality specifications

[b] L = low.
[c] H = high.

of natural gas have been reviewed in both European and North American contexts [338, 339].

8.1.1. Combustion Characteristics

Fuel gases are categorized in one of three families: (1) manufactured gas (high hydrogen content), (2) natural gas and (3) liquefied petroleum gas [340]. Table 42 shows these families and the subdivisions for manufactured and natural gas, within which interchangeability [341, 342] may be assumed. Test gases for evaluation of appliances within these families are described [343].

Other combustion properties are *flame lift* [344 – 346], *incomplete combustion* (yellow tipping) and *flashback* [347].

8.1.2. Minor Constituents

Specifications from several (mainly European) countries have been compared [337]. Typical national requirements for maximum levels of impurities (Table 43) [340] and odorization [348] are described.

Table 43. Recommended limits of gas impurities according to DVGW * Rule G 260 [340]

8.2. Test Methods

8.2.1. Determination of Combustion Characteristics

8.2.1.1. Calorimetry

The calorific value (heating value) H of a fuel gas is defined as the amount of heat released by complete combustion in air, at constant pressure p_1, with the combustion products being returned to the same temperature t_1 as that of the reactants prior to combustion. Normally the *superior calorific value* H_S (synonymous *higher heating value*, HHV) is experimentally determined with all the water formed by combustion being condensed to the liquid state at t_1. The *inferior calorific value* H_I (synonymous *lower heating value*, LHV) is defined as the amount of heat released with all the water formed remaining in the vapor phase at t_1 and p_1.

The calorific value H can be measured or inferred in three ways: (1) direct combustion with measurement of heat released, (2) stoichiometric combustion with measurement of gas – air ratio, and (3) calculation from composition.

Direct Measurement. The calorific value can be measured directly in a *reference calorimeter*, in which the heat liberated from a discrete amount of gas is measured thermometrically [349]. More frequently, however, *continuous recording* calorimeters are used [350 – 354]. The principle of continuous recording calorimeters is combustion of a controlled stream of gas, followed by heat exchange of the products of combustion with another fluid, whose temperature rise is recorded.

Stoichiometric Combustion. Stoichiometric combustion relies upon the constancy of the ratio of calorific value to air – gas ratio for saturated hydrocarbons. For this reason, it can be used for natural gas, but not manufactured gas [355]. Stoichiometric combustion devices have been used as part of an energy flow meter [356], where the rate of supply of gas to the meter is kept exactly proportional to the flow in the main stream from which it is taken.

Calculation from Composition. The composition of fuel gases can be defined very well by gas chromatographic measurement. Knowledge of calorific values for the pure components and an appropriate calculation routine [357, 358] lead to the calorific values H_S and H_I of the mixture.

8.2.1.2. Density

Gas Density Balance. The gas density ϱ (mass per unit volume) or relative density d (ratio of the density of the fuel gas to the density of dry air) [359] is most commonly determined by a gas density balance [360, 361]. The method is based on the buoyancy of a nitrogen-filled sphere in the test gas. Instruments of this type also allow continuous monitoring of gas density.

Oscillating Device. Another method for determining density employs an oscillating device (e.g., a tuning fork). The frequency of oscillation is a function of the density of the gas surrounding it [362].

Both types of density recorders are checked and calibrated by standard gas mixtures of known (e.g., gravimetrically determined) density [363]. Density and relative density may also be calculated from gas analysis [357].

8.2.1.3. Wobbe Index

The Wobbe index W is defined as the ratio of calorific value H to the square root of relative density at the same specified metering reference conditions. As with the calorific value it must be distinguished between *superior Wobbe index* W_S and *inferior Wobbe index* W_I. Normally, the Wobbe index W is not measured directly, although it is one of the most important combustion characteristics for describing gas quality.

Calculation of Wobbe Index. The index can be calculated from the calorific value and the relative density more accurately than by direct determination. The Wobbe index may also be obtained by combining the signals of a calorimeter and a densimeter electronically, according to its definition equation.

Direct Measurement of Wobbe Index. Direct measurement of the Wobbe index with relatively simple and rapid instruments is recommended only for mixing gases of different quality to yield a mixture of constant Wobbe index. These *Wobbe recorders* are automatic calorimeters whose gas flow rate is adjusted so that it is proportional to $1/\sqrt{d}$.

8.2.2. Analytical Methods

The analytical methods listed in the following sections are (1) general methods (i.e., capable of measuring several components, Section 8.2.2.1); (2) specific methods for individual components (Section 8.2.2.2); or (3) methods suitable for minor components (Section 8.2.2.3).

Sampling is the first, and a most important, stage in gas analysis. Therefore, great care should be taken to obtain representative samples for determining gas properties and composition [364]. Continuous automatic sampling techniques have also been developed [365].

8.2.2.1. General Methods for Determination of Several Components

Orsat Method. The main constituents of manufactured gases (CO_2, O_2, CO, unsaturated hydrocarbons, H_2, saturated hydrocarbons and N_2) were determined volumetrically by the classic Orsat method involving successive absorption of the constituents in specific reagents and selective combustion of hydrogen and saturated hydrocarbons [366]. A simplified Orsat apparatus is used at present only for flue gas analysis or in combination with the chromatographic Janak method for carbon dioxide, oxygen, and unsaturated hydrocarbons.

Janak Method. The Janak procedure, which is suitable for manufactured gases as well as for natural gas components up to C_4H_{10}, is a simple chromatographic method using carbon dioxide as carrier gas [367]. The carrier gas emerging from the column passes to a burette filled with concentrated potassium hydroxide solution, in which carbon dioxide is absorbed and the remaining components can be measured consecutively by volume. The apparatus available commercially registers the volume ratio of the different components with an automatic burette.

Gas Chromatography (GC). Besides the Janak method, GC [368 – 370] with a thermal conductivity or flame ionization detector is most often recommended for fuel gas analysis. A large number of standardized methods exist for the analysis of manufactured gas [371] and natural gas [372 – 374] by using an *adsorption column* (e.g., molecular sieve) for the separation of hydrogen, helium, oxygen, argon, nitrogen, methane, and carbon monoxide, and a *partition column* (e.g., organic stationary phase on a solid support) for the separation of higher hydrocarbons. For the analysis of natural gas, determination of hydrocarbons up to pentane [372] or octane [373, 374] is normally sufficient. For specific needs, methods have been developed for analysis up to hexadecane [375].

For onstream applications, these analyses have been completely automated (process GC): this includes periodic calibration of the total system with a calibration gas mixture [376] and evaluation of the chromatogram by an electronic integrator. Gas analyses can also be performed by mass spectrometry [377]. The results of these analyses can be used to calculate the physical, thermodynamic, and combustion characteristics of the gas (H_S, H_I, W_S, W_I, ϱ, etc.) [357, 358].

8.2.2.2. Specific Methods for Determination of Individual Components

Hydrogen. In binary or quasibinary gas mixtures, the hydrogen content can be monitored easily by measuring *thermal conductivity*, because the conductivity of hydrogen is much higher than that of all other likely components.

Oxygen. Besides volumetric [366], chemical [378], and GC methods [373], oxygen (concentration >0.1 vol %) may be determined without significant interference from other components by using instruments based on the measurement of *magnetic susceptibility* [379].

Carbon Dioxide. The carbon dioxide concentration [380] of fuel and flue gases is normally recorded by nondispersive *infrared* instruments [381, 382]. The carbon dioxide absorption band is overlapped only slightly by the carbon

monoxide band, and for a wide range of concentration ratios this interference can be eliminated by using a filter cell containing carbon monoxide. Several instruments are available that use single- or double-beam techniques and different types of detectors. For discontinuous determination, aforementioned volumetric [366] or GC methods [371, 373] may be used.

Carbon Monoxide. *Infrared absorption* is also the recommended method for monitoring the carbon monoxide concentration of gases [383]. Interference from carbon dioxide must be filtered out in the manner described above. Gas chromatography [384] and detector tubes [385] may be used for consecutive measurements or for a single check. Carbon monoxide detector tubes are subject to interference from propane and higher hydrocarbons, which may be found in natural gas. This interference can be eliminated by first leading the gas through an adsorption tube filled with activated carbon.

8.2.2.3. Methods for Determination of Minor Components

Water Content. For discontinuous *gravimetric determination* of water, a drying tube containing a suitable desiccant (e.g., magnesium perchlorate) can be used [386]. Alcohols such as methanol or glycols are also absorbed. Water and methanol (concentration > 20 mg/m^3) can be determined by GC [387].

The *Karl Fischer method* [388], in which water reacts with iodine in an alcoholic solution of sulfur dioxide and pyridine, is suitable for the determination of low water content of the order of milligrams per cubic meter. Newer equipment in which iodine is generated coulometrically [389] is particularly suitable for this application.

A variety of *hygrometers* use different detectors [390, 391], such as *electrolytic cells* with phosphorus pentoxide as absorbent, *conductivity cells* with glycerol [392], a *capacitor* with aluminum oxide as the moisture-sensitive dielectric medium [393], *silicon chips*, and an *oscillating quartz crystal*. By absorption or adsorption of water from the surrounding gas, the electrolytic current, conductivity, dielectric properties, or frequency of oscillation is changed. Better instruments use a sophisticated purge and calibration technique to overcome contamination problems caused by hydrocarbon condensates and other impurities such as glycols or ethanolamines derived from gas treatment processes [394]. Some of these instruments measure water content in parts per million (mL/m^3 or mg/m^3); others indicate dew point temperature.

Although water content and dew point can be related theoretically, some uncertainty exists as to whether this can be applied with any degree of accuracy to uel gases. Measurement from any instrument is more safely related to the technique used for calibration.

Water Dew Point. Because of the risk of hydrate formation [395], gas temperature should not drop below the dew point. The water dew point can be determined directly when a constant stream of gas passes over a polished metal mirror that is cooled slowly [396]. The dew point corresponds to the temperature at which the first signs of condensation appear on the mirror. The measurement can be performed under pressures up to 10 MPa. Completely automated instruments employing photocells are also used [390]. If the gas contains methanol or glycols, the dew point corresponds to the simultaneous condensation of water and alcohol. If the methanol content is known, a correction can be applied to the observed dew point [396]. Condensation of hydrocarbons may also interfere, when the hydrocarbon dew point is higher than that of water. This interference can be reduced significantly by first passing the gas through high-boiling liquid paraffin.

Sulfur Compounds.

Total Sulfur. The *combustion method* is applicable to all fuel gases. A measured volume of gas is burned with excess air or oxygen in a specially designed apparatus (e.g., Wickbold [397], lamp [398], Lingener method [399]). Combustion products are absorbed in an oxidizing solution. The sulfuric acid formed is determined by *volumetric, gravimetric*, or *turbidimetric* methods [400]. Sulfur dioxide can also be titrated *coulometrically* [401].

In the *hydrogenation method*, sulfur compounds are catalytically hydrogenated to hydrogen sulfide at high temperature over platinum gauze in the presence of excess hydrogen and

water vapor. Subsequent determination of hydrogen sulfide by the *methylene blue procedure* is very sensitive [402]. The *lead acetate paper method* in combination with hydrogenation is less precise but can be automated for continuous photometric recording [403].

Simultaneous Determination of Hydrogen Sulfide, Carbonyl Sulfide, and Mercaptan Sulfur. A measured volume of gas is passed through two sets of bubblers in series. The first set contains concentrated potassium hydroxide solution in which hydrogen sulfide and mercaptans are absorbed; the second contains alcoholic monoethanolamine solution, which absorbs carbonyl sulfide. Potentiometric titration with silver nitrate measures each species [404].

Individual Sulfur Compounds. The preferred method for determining individual organic and inorganic sulfur compounds is GC. Although sulfur compounds can be detected by thermal conductivity or flame ionization detectors (the latter for organic sulfur compounds only), sulfur-specific detectors are preferred for the analysis of naturally occurring or added odoriferous sulfur compounds to avoid interference from other components. The *flame photometric detector* [368, 405] measures the light emitted at 396 nm when sulfur compounds are burned in a hydrogen-rich flame.

The *electrochemical detector* widely used for the control of gas odorization registers the potential change of an electrolytic cell when chromatographically separated sulfur compounds are oxidized by concentrated chromium trioxide solution [406]. Carbonyl sulfide, which is not indicated by this detector in its normal mode of operation, may also be detected when potassium hydroxide solution is used instead of chromium trioxide.

The *Hall detector* measures the change in conductivity caused by absorption of sulfur dioxide in an electrolyte after the effluent of the chromatographic column has been burned with excess oxygen by passing the gas stream through a narrow nickel tube at high temperature [407]. The change in conductivity is directly proportional to the sulfur content of the effluent. The same principle has also been used for monitoring the total sulfur content of fuel gases.

Hydrogen sulfide can be determined by the formation of brown or black stains of lead sulfide on lead acetate paper. This can be a simple semiquantitative test, a manual quantitative determination [408], or a completely automated control [403]. For *spot measurements*, detector tubes [385] may also be sufficient. Wet chemical determinations are based on iodometric titration [409] or the very sensitive Methylene Blue method [410]. The coulometric method uses the oxidation of hydrogen sulfide by electrochemically generated bromine. Interference from other oxidizable sulfur compounds can be eliminated by using a difference method with selective absorption solutions (e.g., $CdSO_4$ for H_2S and KOH for H_2S and mercaptans) [411]. Specific electrochemical cells are used for monitoring the hydrogen sulfide concentration in air or fuel gases.

Carbon disulfide is normally determined by GC [368], but colorimetric methods and detector tubes [385] may also be used.

Besides the aforementioned GC and potentiometric methods, carbonyl sulfide can be hydrolyzed in dilute potassium hydroxide solution. The resulting sulfide is determined colorimetrically by the Methylene Blue method.

Nitrogen Compounds.

Ammonia. Ammonia in manufactured gas is determined by absorption in standard sulfuric acid and titration of the excess acid [412]. *Low concentrations* are indicated by reaction with Nessler's reagent, which is also used for colorimetric determination. For *spot measurements*, gas detector tubes are available [385].

Hydrogen Cyanide. Hydrogen cyanide in coal gas with low hydrogen sulfide content can be determined after absorption in a nickel – sodium carbonate suspension [413] or in an ammoniacal solution of zinc sulfate by titration with silver nitrate. Gases with a higher content of hydrogen sulfide can be analyzed by the cyanogen bromide method [414].

Nitrogen Oxides. Nitrogen dioxide forms a red dye with Saltzman solution [415]. Nitric oxide present in coal gas, therefore, must first be oxidized by passing the gas through a sodium permanganate solution. Both oxides can be determined together, or nitric oxide alone, after selective absorption of nitrogen dioxide.

For the analysis of *flue gases*, the chemiluminescent reaction between nitric oxide and ozone is used for NO_x determination. If nitrogen dioxide is included, the gas must pass through a con-

verter where nitrogen dioxide thermally decomposes to nitric oxide and oxygen [416].

Condensable Hydrocarbons. Natural or manufactured gases may contain amounts of condensable hydrocarbons that can cause problems by forming gas condensates. In dry gas, the *hydrocarbon dew point* may be determined by the mirror method [396]. The potential hydrocarbon liquid content in natural gas can be evaluated either by weighing or volumetrically [417].

Gas benzene (i.e., BTX aromatics and higher boiling hydrocarbons) was formerly determined by adsorption on activated carbon and subsequent displacement by steam. Today, chromatographic methods are preferred.

Naphthalene and other condensed aromatic components can be determined chromatographically or in total by precipitation of the corresponding picrates [418].

8.2.2.4. Determination of Trace Constituents

For the determination of trace constituent (e.g., nickel and iron carbonyl, chlorine [419], and mercury [420]), several methods have been developed, using atomic absorption spectrometry (AAS) to determine heavy metals.

1. Introduction

Gelatin is a mixture of high molecular mass polypeptides produced from collagenous animal tissues such as hide splits, pigskin, and bones. Collagen is the most commonly occurring protein in the human and animal body, accounting for about 30 % of the total protein content. Since animal horns and hoofs are not composed of collagen they cannot serve as raw materials, contrary to popular belief. The name gelatin has been used since about 1700 and is derived from the Latin *gelatus* which means frozen [1]. There is evidence that gelatin has been used for at least 4000 years [2]. The great variety of applications of gelatin depend on its solubility in hot water, its availability in a wide range of qualities, and its ability to form thermally reversible gels, which is unique for a protein and is due to the fact that the primary structure of collagen still exists in collagen-derived polypeptides.

2. Structure and Properties

2.1. Structure

Collagen is not a uniform substance but an entire protein family. To date, some 19 polymorphs of collagen have been identified. All types of collagen have a triple-helix structure in which three protein chains are intertwined to form a rigid strand (Fig. 1). The length of the triple helix and the type and position of the nonhelical regions vary from one collagen type to an other.

The "classical" type I collagen, the most important type in the manufacture of gelatin, occurs

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a12_307

in skin and bone. Type II collagen occurs almost exclusively in cartilage tissue, and type III collagen occurs besides type I in skin. The concentration of type III collagen is strongly dependent on age: embryonic skin can contain up to 50 %, but older skin only 5 – 10 %. The other collagen types occur only in low concentrations and fulfil mostly organ-specific functions.

Collagen consists of three helical polypeptide chains wound around each other and connected by intermolecular cross-links. The triple helix is formed intercellularly from three individual chains (α-chains). Chain selection occurs via intra- and intermolecular disulfide bridges in the region of the N- and C-terminal peptides, additionally supported by glycopeptide structural elements. While collagen types II and III contains three identical chains (homotrimer $[\alpha_1(\mathrm{II})]_3$), type I collagen consists of two identical and one somewhat differing chain (heterotrimer $[\alpha_1(\mathrm{I})]_2\alpha_2(\mathrm{I})$). The triple helix molecule is 300 nm long and 1.4 nm in cross section. The amino acid sequences of the α_1 and α_2 chains are highly homologous (ca. 90 % correspondence).

Collagen contains large amounts of two unusual amino acids: 4-hydroxyproline and ε-hydroxylysine, which are the result of post-translational modification: special enzyme systems facilitate the intracellular hydroxylation of proline and lysine on the growing collagen chain. Other enzymes are responsible for the glycosylation of individual hydroxylysine residues. Type I collagen, for example, contains 0.5 wt % carbohydrate, and type III about 10 %. The carbohydrate portion comprises galactose and a 1,2-linked galactose – glucose disaccharide. The ether-like bond between collagen and the saccharide occurs between the C1 atom of galactose and the ε-hydroxyl group of hydroxylysine.

The enzyme-catalyzed modification steps (hydroxylation and glycolyzation) are restricted to growing individual chains; as soon as triple-helix formation is initiated, modification ceases. As stability of the helix is dependent on the hydroxyproline content, helix formation and proline hydroxylation are interdependent and self-regulating.

The helical part of all three collagen types contains 1014 amino acids per chain, and the N- and C-terminal nonhelical extension peptides (telopeptides) are between 9 and 26 amino acids long. The triple helix molecule has a molecular weight of about 290 000, including the short N- and C-terminal globular extension peptides.

Collagen consists of one-third glycine and 22 % of the imino compounds proline and hydroxyproline; the remaining 45 % comprises some 17 other amino acids (Table 1). The content of acidic and basic amino acids is relatively high. About one-third of the acidic amino acids glutamic acid and aspartic acid is present in the amidated form as glutamine and asparagine. Cysteine is completely absent, and of the sulfur-containing amino acids only methionine is present at low concentration (exception: type III which has two cysteine residues per 1000 amino acids).

The "classical collagen" types are characterized by repetitive tripeptide units – (glycine-X-Y-)$_n$ – where proline occurs in the X and Y positions and 4-hydroxyproline exclusively in the Y position. Several other amino acids also have preferred positions, presumably for steric reasons. For example, glutamic acid, phenylalanine, and leucine occur frequently in the X position, and arginine mostly in the Y position. Generally, collagen types from different species are to a high degree homologous (usually about 90 %); and, within the same species, type I collagen from skin, bones, and tendons are identical.

Triple-helix, water-soluble collagen (types I to III) is converted extracellularly by cross-linking and fibril formation into highly associated, water-insoluble collagen. These intra- and inter-molecular cross-links are responsible for a dramatic increase in stability of the collagen molecule relative to thermal, mechanical, and enzymatic influence. The type and extent of the covalent cross-links are age-dependent, an aspect that is of considerable importance for the gelatin industry. Process parameters and extraction conditions must hence be adapted to the age of the raw materials (e.g., young pig or calf skin / old cattle hide).

2.2. Physical Properties

Commercial gelatin is a vitreous solid with a faint color; it is almost tasteless and odorless and usually contains 9 – 13 % moisture. It gives typical protein reactions and is hydrolyzed by

most proteolytic enzymes to give its peptide or amino acid components.

Depending on the degree of hydrolysis, two different types of gelatin are obtained:

1) Gelatin, gelling type [*9000-70-8*]: When the granules are immersed in cold water they are hydrated to discrete swollen particles. On heating, these swollen particles dissolve to form a solution.
2) Gelatin hydrolysate (also known as collagen hydrolysate), nongelling type [*68410-45-7*]: In this product range the molecular mass is reduced to such an extent ($<$ 15000 D) that no gelation is observed. This type, mostly produced as a fine powder is soluble in cold water. Gelatin and gelatin hydrolysate are in-

soluble in less polar organic solvents such as benzene, petroleum ether, ethanol, acetone and tetrachloromethane.

Gelatin and gelatin hydrolysate are insoluble in less polar organic solvents such as benzene, petroleum ether, ethanol, acetone and tetrachloromethane. Gelatin is amphoteric: in acidic solution gelatin is positively charged and migrates as a cation in an electric field; in alkaline solution it is negatively charged and migrates as an anion. The intermediate point, where the net charge is zero and no migration occurs, is known as the isoionic or isoelectric point. Type A gelatin, produced by acidic processing of collagenous raw materials, has a broad isoelectric region between pH 6.0 and 9.5. Type B gelatin, produced by the alkaline processing of collagenous raw materials, has an isoelectric point between pH 4.7 and 5.6. The difference in the isoelectric points of type A and type B gelatins is the result of partial desamidation of glutamine and asparagine to the corresponding glutamic acid and aspartic acid. Mixtures of type A and B, as well as gelatins produced by modifications of the above-mentioned processes, may exhibit isoelectric points outside these ranges. Gelatin in solutions containing no ions other than H^+ and OH^- is known as isoionic gelatin [3]. These solutions can be readily prepared by the use of ion-exchange resins.

One of the most important properties of gelatin (gelling type) is the formation of heat-reversible gels in water. Gelatin readily forms gels over a wide range of pH with a variety of solutes. The formation and stability of a gelatin gel is influenced by a number of factors. When an aqueous solution of gelatin with a concentration greater than ca. 1 % is cooled to about 35 – 40 °C it first increases in viscosity and on further cooling it forms a gel. The strength of the gel depends on concentration and the intrinsic strength of gelatin used, which is a function of structure and molecular mass. Gel formation is not fully understood, but is believed to result from hydrogen bonding; the gelatin molecules are arranged in micelles that form a semisolid gel and bind water. Quantitative measurement of this property is important, both for control and to determine the amount of gelatin required for a given purpose because gelatin is used in many products for its gel-forming properties. Modern theory proposes that the first step in gelation is the formation of locally ordered regions caused by the partial random return (renaturation) of gelatin to collagen-like helices (collagen fold). Next, a continuous fibrillar three-dimensional network of fringed micelles forms throughout the system, probably due to nonspecific bond formation between the more ordered segments of the chains. Hydrophobic, hydrogen, and electrostatic bonds may be involved in cross-linking. Since these bonds are disrupted on heating, the gel is thermoreversible. Formation of cross-links is the slowest part of the process, so that under ideal conditions the strength of the gel increases with time as more cross-links are formed. The total effect is a time-dependent increase in average molecular mass and in order. Renaturation involves association between components (peptide chains) that differ in degree of cross-linking, chain length, and chemical composition [4], [5].

Gelatin is stable for long periods of time when suitably stored in sealed containers, at normal ambient temperatures to prevent ingress or loss of moisture. When gelatin is heated above 45 °C in air at relatively high humidity it may lose its ability to swell and dissolve [6].

Gel Strength is determined with a Bloom gelometer [7], [8], [10–13]. A 6.67 % solution of the gelatin sample is prepared in a special wide-mouthed test bottle, which is then cooled to 10.0 ± 0.1 °C and kept for 17 ± 1 h for maturation at this temperature. The firmness of the resulting gel is then measured with a gelometer. This instrument impresses a standard plunger (12.7 mm diameter, plane surface, sharp edges) into the surface of the gel. The force required to depress the plunger 4 mm into the gel is the gel strength or Bloom value of the gelatin. Commercial gelatins vary from ca. 50 to 300 g Bloom.

Viscosity is usually determined by using a calibrated viscosity pipette (Bloom pipette), which measures the efflux time of 100 mL of a 6.67 % solution at 60 °C.

For gelatin hydrolysate, the viscosity of a 10 % or 20 % solution at 25 °C is determined, but other concentrations or temperatures are possible, according to the different uses. For measurement of higher viscosity values, rotation viscometers are also used.

Molecular mass fractions (≥ 200 000 D) have some impact on viscosity, medium molecular mass fractions (55 000 – 300 000 D) have an influence on gel strength. The viscosity of gelatin solutions increases with increasing gelatin concentration and with decreasing temperature; viscosity is at a minimum at the isoionic point. Gelatin solutions should not be exposed to temperatures above 60 °C for prolonged periods of time because the gel strength and viscosity decrease [14].

Color and clarity of gelatin and gelatin hydrolysate can be important for certain applications. These parameters can be measured with a spectrophotometer, but visual assessment against standard gelatins is also common practice. The color of gelatin depends on the raw material and the production process. Pigskin gelatins usually are less strongly colored than those made from bone or hide. Turbidity may be due to insoluble or foreign matter in the form of emulsions or dispersions that are stabilized by the protective-colloid action of gelatin, or can be caused by an isoelectric haze. This haze is at a maximum at the isoelectric point in ca. 2 % solution [15].

Gelatin typically contains ca. 9 – 13 % *moisture*, which can be determined by drying a sample at 105 °C for 17 h.

Technical gelatins are normally specified by their gelling power and viscosity. The test methods employed are generally similar to those used for edible or pharmaceutical gelatins, but different gelatin concentrations may be employed. For lower grades of technical gelatins (and animal glues) 12.5 % solutions (15 g in 105 mL water) are used.

Methods for sampling and testing of animal glues are described in an international standard [16]. In addition to gel strength and viscosity the measurement of moisture content, melting and setting point, foam characteristics, pH and fat content are also described.

In some countries the viscosity of technical gelatin is measured with a cup viscometer, normally the Engler viscometer [17], [18], [19], and using a 17.75 % solution at 40 °C. The viscosity (in degrees Engler, °E) is the flow time of the gelatin solution compared with that of an equal volume of water at 20 °C. Relationships between viscosity measured by capillary and by the Engler method are available [19], [20].

Gelatin also undergoes a phenomenon called coacervation when colloidal particles separate from the liquid phase. Coacervates are formed when two hydrophilic sols carrying opposite charges are mixed in suitable amounts [21]. If gelatin from an acid-treated precursor is mixed with gelatin from an alkali-treated precursor and the resulting gel is prepared at pH 5 – 7, different degrees of turbidity result. This effect depends on the ratio of the two gelatins in the mixture and the pH. This phenomenon arises from the formation of a complex coacervate between the gelatin micelles with opposite charge. Adjustment of the pH above or below the isoelectric range of both gelatins gives a clear gel; both gelatins are now either positively or negatively charged and hence are mutually compatible. A common application of complex coacervation is the use of gelatin and gum arabic to produce oil-containing microcapsules for carbonless paper manufacture [22], [23] (see → Microencapsulation, Chap. 4.1.).

By addition of plasticizers such as glycerin, sorbitol and lubricants like stearate it is possible to produce a blend with thermoplastic properties that can be used in extrusion and injection molding processes [24].

2.3. Chemical Properties

Gelatin is formed by the particle hydrolysis of collagen protein resulting in a mixture of protein fragments of varying molecular mass (gelatin 15 000 – 400 000 Dalton, gelatin hydrolysate < 15 000 D). The amino acid composition (see Table 1) corresponds to that of the collagen from which it is derived. Hydroxyproline and hydroxylysine are two unusual amino acids found in gelatin. The determination of the hydroxyproline content can be used for identification purposes [25].

The quantitative analysis of the elements gives about 50.5 % carbon, 25.2 % oxygen, 17.0 % nitrogen and 6.8 % hydrogen. The ash content of commercial gelatin varies with the origin of the raw material and the method of processing. Gelatins derived from pigskin contain small amounts of chlorides and sulfates resulting from acid treatment before extraction; gelatin from bone and hide contains calcium and sodium salts from the lime used in pretreatment.

Dry gelatin stored in airtight containers at room temperature remains unchanged for long periods. Degradation in solution may be caused by extremes of pH, temperature and by proteolytic enzymes such as papain or trypsin.

Gelatin can be chemically modified to change its properties. It undergoes typical protein reactions, including acylation and carbamylation [26]. Such products include succinylated, phthalated, and carbamylated gelatin. These products are used for special pharmaceutical and photographic applications. A new type is methacrylated gelatin, which is suitable for technical applications. Permanent cross-linking of gelatin can be achieved by reaction with aldehydes such as formaldehyde, glyoxal, or glutaraldehyde [26].

2.4. Microbiological Analysis

Microbiological testing is in most cases carried out according to methods described in the European Pharmacopeia (Ph. Eur.) and the United States Pharmacopeia (U.S.P.). Important test parameters are total aerobic count, including molds and yeasts, after an incubation period of up to 5 d at incubation temperatures of 30 – 35 °C and 20 – 25 °C and counts of colony-forming units on tryptic soy agar and Sabouraud agar. Tests for *Escherichia coli* and Salmonella species include at least one enrichment step and detection of typical growth on selective nutrition media.

Table 2. Gelatin specifications

Parameter	Ph. Eur. limits	U.S. P. limits
pH	3.8 – 7.6	
Total ash, %	2	2
Loss on drying, %	15	
Sulfur dioxide, mg/kg	200	40 ∗
Peroxides, mg/kg	100	
Arsenic, mg/kg	1	0.8
Heavy metals, mg/kg	50	50
Phenolic preservatives	0	
Total viable count CFU ∗∗	1000/g	1000/g
Escherichia coli	0 in 1 g	0 in 10 g
Salmonella	0 in 10 g	0 in 10 g

∗ Gelatin used for capsule manufacture can contain up to 1500 mg/kg. ∗∗ CFU = colony-forming units.

2.5. Quality Specifications

Gelatin, as a protein, is subject to contamination by microorganisms; good manufacturing practice must be followed to ensure a clean product. In addition to rendering gelatin unacceptable for human consumption, bacteria can degrade gelatin to a point at which it loses its gel-forming property. Conductivity and pH have a major impact on gelatin quality due to their importance regarding optimal growth conditions for bacteria [27].

Most gelatin manufacturing plants meet the strict requirements of ISO 9000 [28] and ensure consistent high quality by the implementation of HACCP (hazard analysis and critical control points) techniques [29]. The result is one of the purest proteins available to the food, pharmaceutical, and photographic industries. As a pure, natural protein, gelatin is a food, not an additive and, does not carry an E number.

The majority of commercial gelatins contain less than 3000 nonpathogenic bacteria per gram. For pharmaceutical-grade gelatin the pharmacopeia (Ph. Eur., U.S.P.) set a limit of 1000 bacteria per gram, and Salmonella species and *Escherichia coli* must be absent in 10 g and 1 g, respectively [9], [10]. Physical and chemical characteristics of gelatin are listed in Table 2, together with microbiological specifications for pharmaceutical-grade gelatin.

Up to now there are no official limits for microbiological, physical or chemical parameters for food-grade gelatin. Therefore the Gelatin Manufacturers of Europe (GME) cooperate with official authorities to set microbiological, physical, and chemical limits for food-grade gelatin. It is planned to release a monograph for food-grade gelatin which contains not only the quality limits but describes also the test methods to ensure compliance with those limits.

Since the raw materials are exclusively obtained from animals fit for human consumption, and the production process includes numerous purification steps like washing, filtration, ion exchange and a final UHT sterilization step, gelatin is a safe product with regard to bacteriological, viral, and TSE (transmissible spongiform encephalopathies, e.g., Scrapie and BSE) safety [30], [31] and therefore does not carry any risk for the health of consumers.

3. Raw Materials and Production

3.1. Raw Materials

Gelatin is commercially derived from animal collagen of skins and bones. The principle raw materials worldwide are cattle hides, bones and pigskins. In principle all raw materials are fit for human consumption. Sources from other mammalian species and fish sometimes are also used. Each raw material requires special treatment to remove noncollagenous extraneous substances such as fat and minerals. The resulting pure collagen is then hydrolyzed to gelatin, which is soluble in hot water.

Bones. The so-called green bones are supplied by slaughterhouses and meat packers. The fresh raw material is transported directly to the degreasing plants of the gelatin producer. After preselection the bones are crushed into small particles, degreased, dried and sorted according to size. The mineral components of bones are hydroxyapatite and calcium carbonate. To remove the inorganic components the bones are treated for about a week or more with cold diluted acid. The resulting collagen is called ossein, the starting material for subsequent gelatin extraction.

Cattle Hides. Skins from calves and beef are obtained from animals slaughtered for human use. The subcutaneous, fat-containing tissue is mechanically separated and the skins are split horizontally into two parts: the part previously covered with hair is tanned and subsequently used as a high-quality leather. The parts previously in contact with the flesh are the so called hide splits. These residual thinner sections remain untanned and are dried or preserved with salt or calcium hydroxide to become the raw material used in the production of gelatin.

Pigskin. Pigskin is the most important raw material for production of edible gelatin in Europe and United States. Pigskins are supplied by slaughterhouses and meat processing plants and are frequently cooled or even frozen to prevent deterioration.

3.2. Production

Each raw material requires a special pretreatment of the collagen containing material to render it soluble in hot water. During pretreatment procedures the collagen swells and softens, peptides and cross-links are hydrolyzed, and various substances, regarded as impurities, are extracted. Two main types of gelatin are distinguished: type A from acid pretreated raw material and type B from alkaline processing. The production process is shown in Figure 2.

Acid Process. The acid process is used for pigskin and sometimes for special types of ossein. Washed pigskins are treated with diluted mineral acids for approximately 24 h at low temperature. This pretreatment is sufficient to break acid-labile peptide bonds in pigskin collagen. After partial neutralization the gelatin is then extracted with hot water. Usually, the gelatin is extracted stepwise with successive increase of temperature and time. Gelatins from successive extractions show different physical and chemical properties. The first extract has the highest gel strength and molecular mass and a very low color. Later extracts, obtained at elevated temperatures, contain a higher amount of low molecular weight peptides and therefore have lower gel strength and are more intensive in color and clarity.

Alkali Process. For the production of type B gelatin, cattle hides and ossein are pretreated with alkali (lime or sodium hydroxide) at ambient temperature. The liming time varies from several weeks to several months. The treatment removes impurities and splits cross links and peptides. The liming time is a critical parameter for the further processing.

The dilute solutions obtained by hot-water extraction contain 3 – 10 % gelatin. The liquors are filtered and deionized to remove suspended matter and undesirable amounts of inorganic ions. The clarified, dilute gelatin solution is concentrated to 25 – 35 wt % by vacuum evaporation, filtered, and sterilized. The concentrated liquor is rapidly chilled to a gel, extruded as noodles, which are deposited on a stainless steel net for drying with hot, sterile air. The net passes

Figure 2. Gelatin production process

slowly through a drying chamber, which is divided into several zones with controlled temperature and humidity. Typical temperature range is from about 30 °C at the beginning up to about 70 °C in the final zone. The dried gelatin, having a moisture content of ca. 10 %, is broken and milled. The physical, chemical and microbiological properties of each extract are tested.

4. Uses

4.1. General Aspects

Although basically a food stuff, gelatin has long been valued not only for its nutritional contribution but also for its functional qualities. Therefore, the use of gelatin is not limited to the food industry. Very important applications are found in the pharmaceutical, cosmetic, photographic and technical area.

The use of gelatin in all these application fields depends largely on the structure function relationships that influence the functionality [33]. The main influencing molecular parameters are:

- Amino acid composition and sequence
- Secondary, tertiary, quaternary conformation
- Net charge and charge distribution
- Hydrophobicity/hydrophilicity ratio
- Size and shape
- Secondary reactions (intra- and intermolecular)
  - Hydrogen bonding
  - Ionic bonding
  - Van der Waal's bonding

The functional role of gelatin does not arise from a single physicochemical property, rather it is a manifestation of a complex interaction of multiple properties. In spite of this the amino acid composition and sequence is the main reason for several functional properties. Gelatin is composed of about 65 % of polar or ionized amino acids. This high proportion of these polar amino acids influences hydration properties such as solubility and water-binding capacity. The type of hydrophobic amino acid residues and the hydrophilicity ratio are associated with amphiphilic behavior, which is important for foaming and emulsifying properties.

Due to its molecular structure and its structure – function relationship gelatin, shows the following properties:

- Gel formation
- Water binding
- Thickening
- Emulsion formation and stabilization
- Foam formation and stabilization
- Film formation
- Adhesion / cohesion
- Protective colloid function

4.2. Food Industry

Edible gelatin and gelatin hydrolysate are widely used ingredients in the production of food. Different properties and different applications require the production of suitable gelatin types [32]. Because of the ease of measuring out the required quantity, *leaf gelatin* is sold worldwide for household use. For cream cakes and cream desserts, special instant gelatins are available for preparing foods without heating. In the food industry powdered gelatin and gelatin hydrolysate are used in the processing of confectionery, dairy products, desserts, meat products, beverages, and so on.

Confectionery. For the confectionery industry, gelatin and gelatin hydrolysate are used due to their different properties:

- In the production of gums and jellies, gelatin is responsible for gel formation, texture, and the bright shiny appearance.
- Aerated confectioneries such as marshmallows owe their light and soft character to the ability of gelatin to form and stabilize foams.
- In fruit chews, gelatin or gelatin hydrolysate is used to prevent products becoming sticky.
- The film-forming properties of gelatin are used in the production of dragees.
- In caramel and liquorice sweets, gelatin provides excellent texture and mouthfeel.
- In pastilles, an elastic structure and excellent melting properties are provided by gelatin.
- In lozenges and compressed products, the binding properties of gelatin guarantee retention of shape.

Dairy Products. Gelatin enhances the texture of dairy products in an optimal way. Many product properties can be controlled by using different quantities and types of gelatin:

- Gelatin acts as a protective colloid in yogurts, thus preventing syneresis. The consistency can be adjusted from creamy to almost solid.
- Soft cheese can be adjusted in consistency from creamy to sliceable.
- Cream and toppings can be stabilized to retain their shapes.
- Sour cream retains its spreading and good melting qualities.
- The ability of gelatin to bind water, form emulsions and provide stability is exploited in the production of low-fat dairy products.
- The melting behavior of ice cream is substantially enhanced by the improved emulsion and finer crystal structure made possible by the addition of gelatin. In this application, gelatin is frequently combined with other hydrocolloids.

Desserts. Crystal-clear, firm to soft gels are required for dessert and fruit jellies; these can be fulfilled by selecting the most suitable gelatin type. In the production of whipped mousse and cream desserts, excellent foam formation and stability of the gelatin are important selection criteria. Different types of instant gelatin with different gelling properties can be used in the production of ready-to-eat desserts, both in mass production and in the households.

Meat and Sausage Products. Gelatin is used as gelling agent in the production of crystal-clear aspic meat and sausage products. Depending on the gelatin type the texture of the gel can range from soft to sliceable. In addition gelatin guarantees the brilliance and color of these products. Nongelling gelatin hydrolysates are used in edible dips and in combination with gelatin as adhesives in meat and sausage coatings.

Additionally both gelatin and gelatin hydrolysate are used to optimize the following technological and sensory quality parameters:

- Reduction of jelly and fat residues in canned sausage
- Improvement of spreading, quality, and softness in emulsified sandwich spreads
- Whipping agent for low-calorie sandwich spreads
- Improved homogeneity of binding in cooked sausage
- Protein enrichment in cured meats
- Rapid reduction of a_w values (water activity, see → Foods, 2. Food Technology, Chap. 1.4.) and shorter maturation times in raw sausage preparations
- Stabilization of emulsions, dispersions and suspension

Beverages. Gelatin and gelatin hydrolysate are used for the clarification of beverages, especially wine, fruit juices and beer. Clarification removes, substances causing turbidity and/or bitterness and have a detrimental effect on optics and taste. Secondly, such pre-clarification can enhance the efficiency of subsequent centrifugation. If necessary, gelatin treatment can be enhanced by adding silicic acid solution or bentonite. This helps to give the wines and juices the desired degree of brilliance.

Bakery Products. In the bakery industry, powder gelatin, leaf gelatin and instant gelatin are primarily used for the binding or gelling of fillings, as well as for the stabilization of creams.

Other Food Applications. Other industrial uses of gelatin in the food area are:

- Binder and gelling agent in canned seafood and seafood aspic products.
- Protein enrichment of food such as in beverages and dietetic products.
- Film former in panned confectionery products such as sugared almonds and hard-panned chewing gum varieties.
- Stabilizer and film former in icings and glazings for bakery products.
- Thickener and emulsifier in soups, sauces, and gravies.
- Emulsifier in half-fat margarines and butter.

4.3. Pharmaceuticals

Gelatin is widely used in the pharmaceutical industry: for the manufacture of soft and hard capsules, as a bulking agent for the coating of water-insoluble vitamins, as a starting material for the

production of human plasma expanders, as a primary component for surgical sponges and as a binder in tablets. In addition to its use as an excepient (i.e., auxiliary agent in pharmaceuticals, see above) gelatin is recommended as a food supplement in the case of joint diseases.

The highest demand for pharmaceutical gelatin is for the production of soft and hard capsules. Soft capsules are made by feeding two plasticized gelatin ribbons between two revolving dies. Pharmaceuticals – either as a liquid or dispersed in an oil – are injected into the capsules as they are formed. Subsequently the capsules are dried in a two-step process.

Gelatin types used for the manufacture of soft capsules are 150 – 175 Bloom limed bone or limed hide, 190 – 210 Bloom acid pigskin or acid bone or a blend of 150 – 170 Bloom acid pigskin / limed bone and hide gelatin. Viscosities are in the range of 2.8 – 4.5 mPa · s. Acid-processed hide and bone gelatin types are preferred for water-miscible or hygroscopic contents. Due to their lower viscosity, less water can be used for the gel mass formulation. Glycerin or polyhydric alcohols like sorbitol are frequently used as plasticizers. In general, the gel mass is composed of 40 – 50 % gelatin, 20 – 30 % plasticizer and water.

Hard capsules, consisting of gelatin, dyes or pigments, and sometimes some processing aids, are produced as two separate parts, known as bodies and caps, by dipping stainless steel pins into a preheated 25 – 30 % gelatin solution. Dried and prelocked hard capsules are forwarded to pharmaceutical companies or contract laboratories to be filled mainly with powdered or granulated pharmaceuticals and sealed. Gelatin types used for the manufacture of hard capsules are 220 – 260 Bloom limed bone or blends of 220 – 260 limed bone / acid pigskin gelatin types. The use of gelatin to coat tablets is a growing market. In a process similar to the manufacture of hard capsules, the tablets are dipped into a concentrated gelatin solution and dried. In another process, the tablets are pressed into prefabricated hard capsules and sealed. Gelatin capsules and coatings protect pharmaceuticals from moisture, oxygen, and microbial deterioration.

Low-bloom gelatins (70 – 140 Bloom) are frequently used to coat vitamins A, D, and E for animal feed and human vitamin preparations. Emulsions of oil-soluble vitamins in gelatin solution containing carbohydrates are spray-dried to give free-flowing powders. Vitamins are thus available in a convenient and stable form that offers protection from light and oxidation.

Specially processed gelatin types have been successfully used as plasma extenders capable of maintaining osmotic pressure. The osmotic pressure of gelatin is strongly dependent on the average molecular weight. Thus the retention time of the plasma extender (generally: 24 – 48 h) is influenced by the size of the molecules. Commercial products are manufactured by partial thermal degradation of high-bloom limed bone gelatin, followed by chemical modification with succinic anhydride or cross-linking the resulting polypeptides with glutardialdehyde or isocyanates. Products containing ca. 3 % of degraded and modified gelatin are liquid at room temperature. Hemostatic sponges are manufactured by whipping a sterile gelatin solution into a foam, which is rendered insoluble by adding formaldehyde on drying. Gelatin sponges impregnated with thrombin can be left in place after surgery or extraction of teeth. Proteolytic enzymes completely digest the sponge.

Gelatin can act as a binder in the manufacture of tablets. Pharmaceuticals are dispersed in a gelatin solution and dried. The ground powder is subsequently compressed into tablets. Glycerin/gelatin masses are used for the production of zinc / gelatin dressings and suppositories.

4.4. Cosmetics

Gelatin and more frequently its hydrolysates find wide application in skin and hair-care products. Hydrolyzed collagen is nontoxic and produces no skin irritation, sensitization, or phototoxicity.

In skin-cleansing preparations, gelatin or gelatin hydrolysates reduce the irritation potential of anionic surfactants.

Due to their affinity to hair keratin, gelatin hydrolysates protect the structure of hair. Particularly in preparations for permanent waving, bleaching, or coloring damage of hair structure can be minimized.

4.5. Photography

Gelatin is an important raw material for all silver halide based photographic materials. For this application mostly alkaline-processed bone gelatin types are used. As a hydrocolloid and a polyelectrolyte, gelatin controls growth of silver halide crystals and prevents coagulation [34]. In addition, gelatin contains substances which influence the photographic properties of the light-sensitive material [35]. Gelatin also stabilizes hydrophobic additives in formulations (e.g., dye couplers) [36], [37]. The ability to undergo reversible sol – gel transition combined with the rheological properties of gelatin enable coating of several emulsion layers at the same time on a paper or film base [38], [39]. Gelatin can be cross-linked by a variety of chemical substances [40] to increase mechanical strength and stability of the coated layers to higher temperatures under acid or alkaline conditions without losing the ability to swell. Therefore chemicals can still diffuse through the different layers. This is essential for the development of the latent image and dye formation during processing of the exposed photographic material.

According to their application and their use in photographic materials, gelatin can be classified as follows:

- Emulsion gelatin
- Oil-in-water emulsion gelatin
- Support gelatin

Emulsion Gelatin. During the *precipitation* of the silver halide crystals, gelatin acts as a protective colloid. It stabilizes the silver halide crystals and influences their growth and their crystal habit. For this application highly purified lime-treated bone gelatin is used to prevent contamination of the silver halide by photographically active substances that may otherwise be present in gelatin. Specially modified gelatin may be used as well. By adjusting the pH, the modified gelatin forms a coacervate. This process is reversible and allows washing of the emulsion.

During *chemical ripening*, gelatin is used to control chemical reactions of added components with the silver halide surface in order to achieve desired photographic properties (e.g., sensitivity and contrast). Since gelatin itself could contain sensitizing or restraining substances, a consistent manufacturing process with a reliably high level of purification is required.

Oil in Water Emulsion Gelatin. Gelatin is used to aid formation of stable dispersions of organic substances (e.g., dyes and color couplers) as finely dispersed oil droplets. For this application the surface active properties of gelatin are important.

Support Gelatin. The physical properties of support gelatin are more important in these application areas than the chemical properties. In antihalation and antistatic coatings gelatin serves as a binding medium for light absorbing and electrically conducting materials. Other uses are as follows:

Before a photographic emulsion is applied to a film base, adhesion must be provided between the hydrophobic base material and the hydrophilic gelatin emulsion. For this purpose so-called *scrubbing gelatin*, mixed with organic solvents or acids, is applied to the substrate as an intermediate layer [41]. Gelatin used for this application must be free of any electrolytes that can flocculate with the organic solvents.

Backing gelatin is applied as an additional layer on the back side of the film base to prevent curling, which is caused by the different swelling and shrinkage behavior of the emulsion coatings and the film base material.

Top-coat gelatin is an abrasion-resistant layer which protects the emulsion layers against mechanical stress, rupture, and friction. For some applications, a glossy surface may also be desirable.

Baryta gelatin is used as a nearly colorless binder for a suspension of barium sulfate which is applied to photographic papers in order to provide a highly reflective white appearance.

4.6. Technical Gelatin and Glue

Technical gelatin is a convenient term for gelatin that is used for nonedible purposes. Chemically, like pure gelatin, it is a mixture of proteins obtained by partial hydrolysis of waste collagen from animal connective tissue, bone, and skin. Technical gelatins, however, usually have inferior physical properties (gelling strength and

viscosity of standard aqueous solutions, measured under standard conditions) and contain a higher proportion of nonprotein material than pure gelatin. The nonprotein component varies with the origin of the raw material and is usually residual mucopolysaccharides and soluble inorganic salts arising from the animal protein waste from which the gelatins are derived.

Technical gelatin has many applications based on its gelation and surface properties, for example: adhesives, remoistenable adhesive tapes, abrasives, matches, paper impregnation, plaster manufacture, production of stabilizers for emulsions, flocculation agents, and many more.

4.6.1. Matches

Only very clean glues are suitable for the production of matches, where they are applied as a binder for the matchhead composition. The inclusion of very fine air bubbles in the matchhead is very important to ensure the presence of additional oxygen and good ignition behavior. Therefore the glue must show well-defined foaming behavior as far as stability and structure of the foam is concerned. Special test methods and instruments have been developed to control these important properties. As fat and grease act as undesirable defoamers, they must be carefully eliminated during production. Furthermore, the glue should contain only very small amounts of salts. Especially chlorides lower the setting point of the glue. In countries with high humidity in the air this leads to softening of the matchhead, rendering ignition more difficult or even impossible. Cross-linking with other components of the matchhead may counteract this undesirable performance to a certain extent. Technical gelatin, due to its high gelation power, is also used as an adhesive to produce the slide cover of the matchbox, which is produced at speeds of several thousands of pieces per minute.

4.6.2. Coated Abrasives

In coated abrasives technical gelatin is used as a binder between the paper substrate and the abrasive component. Gelatin-impregnated papers and unglued papers are used as substrates. Usually two coats are applied by two-roller coating devices. As a base coat a concentrated warm gelatin solution is used to apply a thick adhesive film with good spreading behavior and good flat-lying properties. To achieve good spreading properties, gelatin with certain thixotropic properties is required. In some cases starch is added. After the first coat the abrasive material is added, and a high-voltage electric charge is used to align the particles to improve the abrasive performance.

In addition to gelatin fillers, the second coat may contain pigments and additives with a cross-linking effect to toughen the dried film and to reduce moisture sensitivity, thereby increasing the life cycle of the coated abrasive. The coated paper is usually dried in loops in an oven. Compared with abrasive materials coated with phenolic resins, gelatin provides better and more elastic binding to the substrate. A disadvantage is the lower water resistance. The main application for gelatin coated abrasives is therefore the traditional glass or sandpaper used for smoothing wood, leather, and paint surfaces.

4.6.3. Paper Sizing

Technical gelatin is utilized as a size coating in the production of high-quality all-wood, rag – wood, and rag-based papers:

- Currency and other security papers must possess high performance for multiple use, good moisture and abrasion resistance, and good adherence to printing inks.
- In aquarelle papers gelatin provides the desired reduction in surface fluff.
- Most hand-made papers contain gelatin as sizing agent.

4.6.4. Adhesives

Gelatin has many functions in the adhesive field. A rough surface is required to allow mechanical grab of the glue, and at least one substrate must be permeable to water vapor to accomplish proper bonding. Gelatin glues are generally applied as a solution at ca. 60 °C. They have a unique two-step setting behavior. If applied in

normal thickness to a substrate at room temperature, gelation takes place within parts of a second. A bond is formed which will allow handling of the joined materials almost immediately. The much higher final strength and the high temperature resistance (up to 190 °C) comes after complete evaporation of the free water.

Modified gelatin glues with special additives to develop the desired properties are used for:

- Bookcase making on fast-running machines, where stiff cover materials with high resilient strength must often be turned in.
- Book-spine reinforcement: Gelatin gives the book spine the necessary stability. It is also suitable for bonding the gauze or other material. The glue has to form an elastic film after drying and should have good adherence to previously applied synthetic dispersion glues.
- Lamination of paper to cardboard: glue based on gelatin exhibits good flat-lying properties and long open pot life, and only very little shrinkage of the paper is observed. It is used for the production of posters, jig saw puzzles and games.
- Box covering: cardboard boxes are covered with decorative cover materials. The gelatin-based glue must have good flat-lying properties and strong gelation power.
- Gummed tapes and papers: here often unmodified warm gelatin solutions are used. It is important to dry the solution with hot air to form a glasslike film which can be activated with cold water.
- Musical instruments and furniture: only for high-quality products gelatin based glues are still used today. In mass production, synthetic dispersion glues have replaced technical gelatin.

4.6.5. Other Uses

- Very fine ground gelatin is combined with gypsum to provide special rheological properties to surfacer compounds.
- Gelatin is employed for partly replacing casein in glues.
- Gelatin films exhibit antifogging behavior and are therefore used in the production of gas masks.
- As gelatin films are nonflammable, they are used for compostable grave lights.
- The resistance of gelatin to most organic solvents opens up applications in paintbrush production and the manufacture of paper gaskets.
- Gelatin is used in rubber mixtures to smooth the surface.

5. Economic Aspects

The gelatin market in total has shown only a moderate growth of about 2 to 3 % per annum over the last 25 years. Nevertheless, large differences could be seen from year to year with regard to different areas of application or geographical regions. Pharmaceutical use of gelatin in the late 1990s increased by more than 10 % per year in North America, South America, and the Far East, but there was practically no growth in Europe. The use of edible gelatin declined in the Far East and showed no growth in Western Europe.

Worldwide production of high-grade gelatin in 1997 was ca. 245 000 t and ca. 50 000 t of technical gelatin (glue). The distribution of the production is listed in Table 3.

Table 3. Gelatin production by region (in 10^3 t)

Territory	Gelatin	Technical gelatin (glue)
Western Europe	110	8
North America	42	
Asia/Australia/Africa	43	30
Latin America	42	9
East Europe	8	3

The raw material situation is summarized in Table 4.

Table 4. Raw materials for gelatin in production

Raw material	Gelatin	Technical gelatin (glue)
Pigskin	38 %	10 %
Bones	33 %	40 %
Hide splits	29 %	50 %

The worldwide market shares of the different applications were the following:

Edible gelatin	55 %
Pharmaceutical gelatin	17 %
Photographic gelatin	11 %
Technical gelatin (glue)	17 %

Regarding production capacity the leading manufacturers rank as follows:

High-grade gelatin

1) Deutsche Gelatine-Fabriken Stoess AG, Germany
2) SKW Biosystems, France
3) Leiner Davis Gelatin International, Australia
4) Tessenderlo B.V., Belgium

Technical gelatin (glue)

1) Fritz Häcker GmbH & Co., Germany
2) Trobas B.V., Netherlands
3) Ind. Cola e Gelatina Campo Belo Ltda., Brazil
4) Colas e Gelatinas Rebière Ltda., Brazil

Abbreviations :

A glossary of special terms is given at the end of the article (Chap. 7).

A	adenosine
AIDS	acquired immune deficiency syndrome
ADH	alcohol dehydrogenase
ARS	autonomously replicating sequence
bp	base pair
BKV	bovine kidney virus
BPV	bovine papilloma virus
cDNA	copy DNA
C	cytidine
CEN	centromere DNA
CHO	Chinese hamster ovary
cos	cohesive
CSF	colony stimulating factor
dA	deoxyadenosine
dC	deoxycytidine
dG	deoxyguanidine
dT	deoxythymidine
DHFR	dihydrofolate reductase
DNA	deoxyribonucleic acid
DNase	deoxyribonuclease
EGF	epidermal growth factor
FGF	fibroblast growth factor
G	guanosine
GF	growth factor
IL	interleukin
kb	kilobase
lac	lactose
lpp	lipoprotein promoter

LTR	long terminal repeat
MLV	murine leukemia virus
mRNA	messenger RNA
MSV	murine sarcoma virus
ompA	outer membrane protein A
ORI	origin of replication
PDGF	platelet derived growth factor
PGK	phosphoglycerate kinase
rDNA	ribosomal DNA
RFLP	restriction fragment length polymorphism
RNA	ribonucleic acid
RNase	ribonuclease
SV	simian virus
T	thymidine
Tag	SV40 T antigen
Ti	tumor-inducing
TNF	tumor necrosis factor
t-PA	tissue plasminogen activator
tRNA	transfer RNA
trp	tryptophan
UPE	upstream regulatory element
vir	virulence

1. Introduction

Genetic engineering or recombinant deoxyribonucleic acid (DNA) technology has almost become a household word. The concept of genetic manipulation of living organisms is not new. Early horticulturists, animal breeders, and microbial geneticists practiced the science without today's detailed knowledge at a molecular level. The awesome precision of the new technology developed by modern molecular biologists has raised heated debates in recent years concerning its possible benefits and dangers.

Historical Aspects. Deoxyribonucleic acid, the genetic material that determines heredity, was first isolated in 1869, by the German scientist Miescher. When DNA was later discovered to consist of only four basic components, it was generally disregarded as a candidate for genetic material because it was simple. Seventy years after the first successful isolation of DNA, Avery conducted his historic DNA transformation experiments with *Pneumococcus,* which proved that DNA and not protein carried genetic information [9]. The discipline of modern molecular biology came into existence in 1953 when Watson and Crick published their brilliant elucidation of DNA structure based on X-ray crystallographic data [10]. The remaining pieces of the puzzle rapidly fell into place. Messenger ribonucleic acid (mRNA), transfer RNA (tRNA) and ribosomes were characterized and their functions elucidated. The mysteries of DNA replication and DNA synthesis were revealed. Major discoveries leading to the rapid development of recombinant DNA technology were the establishment of conditions and rules governing DNA hybridization [11], the existence and purification of DNA restriction enzymes [12], elucidation of the genetic code [13], and the discovery of DNA ligase [14], an important enzyme that enabled in vitro joining of DNA fragments. In 1972, DNA cloning methodology using the above techniques was put into effect by Boyer, Cohen, and Berg [15].

The powerful potential of this technology was immediately apparent to the medical and pharmaceutical community, although genuine, well-meaning concern existed over its misuse. As a result, leading scientists and representatives of government and industry in the United States met in 1975 at Asilomar to draw up a referendum governing the conduct of genetic engineering experiments in academia and industry. The Recombinant DNA Advisory Committee (RAC) was formed. This committee publishes rules and regulations for recombinant DNA experiments in the Federal Register of the United States annually.

In the United Kingdom, guidelines are formulated by the Genetic Manipulation Advisory Group (GMAG), but enforcement is under the jurisdiction of the Health and Safety Executive (HSE). In Switzerland the Commission of Experimental Genetics oversees recombinant DNA research, whereas in Japan this is the task of the Ministry of Education. In the Federal Republic of Germany, the Central Commission for Biological Safety promulgates guidelines for recombinant DNA research.

2. DNA Cloning Techniques

The first major step in cloning, (i.e., replicating) a gene is to be able to isolate and manipulate a copy of the gene. Several different routes may be

followed in cloning, depending on such factors as the information available about the base sequence of the gene, the amino acid sequence of the protein for which it codes, and the functional activity of the protein. Some standard cloning techniques are described in this chapter. They are based either on cloning DNA fragments in *Escherichia coli* or on synthesizing copy DNA (cDNA). The choice of cloning system is strictly dictated by the method of detection available.

The basic steps in gene cloning are outlined in Figure 1. The "foreign" DNA is cut with a specific enzyme known as a *restriction endonuclease,* in this case *Bam*HI. The resulting fragments are joined in vitro to a plasmid vector at a unique restriction endonuclease recognition site (*Bam*HI) by using DNA ligase. Generally, the recognition site lies within a drug-selection marker (e.g., for tetracycline resistance, Tet^r); this facilitates identification of the clone because insertion of DNA into this site inactivates drug resistance. The resulting recombinant plasmid is transformed (i.e., transferred) into bacteria (*Escherichia coli*), and the recombinants are screened by plating on selective drug media. In the case illustrated, the *E. coli* is first plated on medium containing ampicillin to select the ampicillin-resistant organisms. The tetracycline-sensitive, ampicillin-resistant recombinant clones are then detected by comparing replica plates, one containing ampicillin and the other tetracycline. Because the plasmid vector replicates at a high rate, large quantities of cloned DNA can be purified from a bacterial culture. Similar steps are involved in cloning a gene in yeast cells. For a comprehensive account of cloning vectors, see [16]; for genetic loci, see [17].

Most cloning techniques have been refined extensively and are available as convenient kits from several companies. For a description of the enzymes used in genetic engineering, see → Enzymes, Chap. 6.

2.1. Cloning Genomic DNA Fragments in *Escherichia coli*

One of the first requirements for cloning is the availability of a vector that can carry an extraneous fragment of DNA in an autonomous fashion. Therefore, a vector must be an independent replicon, i.e., a single, autonomously replicating genetic unit. It may be a plasmid, a bacterial virus (bacteriophage) such as lambda or M13, or a cosmid. Each of these vectors is easily distinguishable from the genomic DNA of *E. coli* and, hence, easy to purify and manipulate. They all have specific advantages, and choice of a system usually depends on the size of the DNA to be cloned. For short fragments, a few kilobases (kb) in length, a plasmid cloning system is generally adequate. Bacteriophages such as lambda or M13 are excellent for cloning 10 – 15-kb stretches of DNA. For longer DNA fragments of 30 – 40 kb, the cosmid approach is highly recommended.

2.1.1. Plasmids as Cloning Vectors

Plasmids are circular, double-stranded, autonomously replicating, extrachromosomal DNA elements common in several species of bacteria. For the purpose of cloning, a plasmid must have certain features, the most important being a *small size* and a *relaxed mode of replication,* which confer a higher copy number on the plasmid. In the relaxed mode, plasmid replication is independent of chromosomal replication. Consequently, the plasmid continues to replicate even during the stationary phase following chromosomal replication. In addition, one or more *selection markers* are useful for both selection of the transformants and maintenance of the plasmid. The selection markers are usually genes that code for drug resistance (e.g., tetracycline resistance, ampicillin resistance). Alternatively, they may be auxotrophic markers; in this case, the transformants are unable to synthesize certain substances (e.g., the amino acids leucine or tryptophan) and cannot grow on media that lack these compounds. The plasmid must carry unique *restriction enzyme sites,* some of which should be located within a selection marker.

An extensive list of cloning vectors is given in [18]. One of the most widely used plasmids is pBR322 [19] (Fig. 2) or its derivatives. Deoxyribonucleic acid from the desired source is cut at specific sites with an appropriate restriction enzyme. More than 100 restriction endonucleases are now available; they are described in detail in → Enzymes, Chap. 6.1. In nature, these enzymes prevent illegitimate recombination of

Figure 1. Cloning of foreign DNA in *Escherichia coli* by using a plasmid vector and the restriction endonuclease *Bam*HI
Amp^{r} = ampicillin resistance gene; *Tet*^{r} = tetracycline resistance gene

endogenous DNA with any extraneous foreign DNA by degrading it. They recognize very specific base sequences in DNA, usually four to six nucleotides long, and cut open the double DNA strand to produce two single-stranded overhangs, also known as sticky ends (Fig. 3). Therefore, restriction endonucleases provide not only a means of cutting the source DNA into specific fragments but also a means of recognizing and inserting DNA into the vector. Insertion into the vector can be performed within a selection marker to facilitate selection of recombinant clones by insertional inactivation of the marker, or it may be achieved by directional cloning. In directional cloning the source DNA fragment is cut with two enzymes (e.g., *Hin*dIII and *Bam*HI)

and inserted into a vector cut with *Hin*dIII and *Bam*HI, for both of which it carries unique sites. Because the *Hin*dIII and *Bam*HI recognition sequences are not compatible, the vector ends do not ligate. However, the DNA fragment that does have both cohesive (compatible) ends is inserted in a specific orientation within the plasmid. The circular ligated plasmid transforms *Escherichia coli* with a high frequency, and the recombinants can be picked by means of a selection marker.

2.1.2. Bacteriophage Lambda as a Cloning Vector

A virus that infects a bacterial cell is known as a bacteriophage or, simply, phage. Bacteriophage lambda (λ) is a complex lysogenic phage of *Escherichia coli*. It is, however, one of the most well-characterized phages both genetically and physiologically [20], having a typical head-and-tail structure (Fig. 4). The λ genome is a double-stranded linear molecule about 47 kb in length. Each end of the DNA carries 5′ overhangs that are complementary to each other and contain 12 nucleotides. Upon injection into the *E. coli* cell, these cohesive ends, appropriately termed *cos L* and *cos R,* come together and circularize the genome. Replication of the DNA occurs via a bidirectional mode, and the head-to-tail, tandemly arranged DNA (concatenate DNA) is packaged into the head (Fig. 4). The DNA is cut at the *cos L* and *cos R* sites by a protein coded by λ gene *A*. Assembly of the tail with the head completes the formation of an infectious phage particle, which is released by lysis of the host cell. This is called the *lytic cycle.* Alternatively, the phage can also undergo a *lysogenic cycle* in which it is integrated into the host genome and exists as a stable prophage.

The lytic cycle has been adopted for cloning purposes by isolating appropriate mutants of the λ phage. The process has now been so simplified that the various components are supplied commercially as kits by several companies such as Invitrogen, Amersham, Pharmacia, Stratagene, and Clonetech.

Figure 3. Recognition sequences of *Eco*RI, *Bam*HI, *Hin*dIII, and *Pst*I
The line drawn through the double-strand sequence indicates sites at which the enzyme cuts. Note that *Eco*RI, *Bam*HI, and *Hin*dIII yield 5′ overhangs, whereas *Pst*I yields a 3′ overhang.

For lytic infection, only about 60 % of the λ genome is essential. This includes the left arm, which carries the genes $A-I$ for the head and the tail proteins, and the right arm, which carries the λ rightward promoter (pR) and the *cos R* site. The middle portion is involved in replication and lysogeny, and is not crucial for the lytic cycle. This feature is important because it allows this portion to be replaced by a "foreign" DNA fragment.

Figure 4. Lytic and lysogenic life cycles of the lambda (λ) phage

To permit introduction of "foreign" DNA, the wild-type λ phage has been modified so as to have a single target recognition site for a restriction enzyme (*insertional vector*) or a pair of such sites that allow part of the phage fragment to be replaced by the insert (*replacement vector*). Several variants of such vectors were constructed by BLATTNER [21], who appropriately named them *Charon phages* after the mythological greek ferryman.

Two of the most popular vectors of which several derivatives are now available are λgt10

and λgt11 [22]. The λgt10 vector contains a single *Eco*RI site in the *CI* gene [23], which codes for the repressor of the phage lytic cycle. Insertion at this site inactivates the *CI* function. As a result, recombinant vectors (CI^-) produce clear plaques, whereas nonrecombinant vectors (CI^+) slow down the growth of the host to produce turbid plaques when grown in *E. coli.* Recombinants derived from λgt10 cloning are usually screened by using nucleic acid hybridization (see Section 3.1). For λgt11 [24], the *Eco*RI site is located within the *lacZ* gene which codes for the enzyme β-galactosidase. Therefore, insertion into this site inactivates the *lacZ* gene. In this case, when grown in *E. coli* that cannot ferment lactose (lac^-), the recombinants can be distinguished on the basis of their ability to form colorless plaques on X-gal plates carrying the chromogenic substrate 5-bromo-4-chloro-3-indolyl-β-D-galactoside (X-gal) [25]. A functional *lacZ* gene results in the formation of dark blue plaques due to the hydrolysis of X-gal. Recombinant phage particles obtained in this manner are generally representative of a single genetic source, such as the *E. coli* genome, human genome, or hamster genome, and are called *libraries.* In the case of λgt11 libraries, the *lacZ* protein is expressed. Insertion of a cDNA sequence (see Section 2.2) into the coding region of the *lacZ* gene results in a chimeric or fusion protein, whose proximal end represents part of the *lacZ* protein. Because the "foreign" DNA is then expressed as a protein, the λgt11 libraries can be screened for a particular protein by means of a specific antibody.

Almost every practicing scientist prefers to obtain his or her λDNA in a ready-to-use package. Most companies provide the λDNA as precut left and right arms, which obviates the need to perform this in the laboratory. Thus, genomic DNA fragments or cDNA fragments with appropriate ends can be ligated directly into the arms. The ligated DNA is then packaged into the phage particle. A minimum limit exists for the length of DNA that can be packaged into the λ head. The packaging efficiency decreases dramatically when the insert size is more than 105 % or less than 78 % of the phage genome size [26]. Therefore, if the two arms were ligated directly with each other, they would be packaged very inefficiently.

The success rate in cloning a gene is tied intimately to the final number of recombinant plaques screened. To obtain a complete library, at least 10^6 plaques are required, which is difficult to achieve by transfection of competent bacteria. However, use of an in vitro system for packaging phage DNA into empty phage heads and direct infection of the host cell yield nearly 10^6 recombinant plaques per microgram of ligated vector DNA. The in vitro packaging system consists of cell extracts of two kinds of heat-induced lysogenic strains. One of these is a *tail donor strain* and has a mutation in gene *D,* one of the genes required for head assembly. The other strain is a *head donor strain* and has a mutation in a gene required for tail assembly (gene *E*). Each of these is independently incapable of forming phage particles; in the mixed extract, however, genetic complementation occurs and exogenous DNA is packaged in the phage heads [18].

2.1.3. Cosmids as Cloning Vectors

Cosmids are a cross between the λ phage and a plasmid vector; they contain the *cos* site (hence the name cosmid) of a λ phage ligated into a plasmid vector [27]. Thus, "foreign" DNA can be inserted into a cosmid at a target site. Upon infection of *E. coli,* the cosmid circularizes but replication follows the autonomous plasmid mode and no infectious particles are produced because these functions are not encoded on the vector. The resulting DNA can be packaged into phage particles by using the in vitro packaging system described in Section 2.1.2. Recombinant selection may be based on a drug-selection marker encoded on the plasmid backbone.

Cosmids are extremely useful for cloning very large eukaryotic genomic fragments. Because the size of the parent vector is several times smaller than that of λgt10 or λgt11, for example, a very large foreign DNA fragment may be inserted and packaged with efficiency in the phage particles.

2.1.4. Bacteriophage M13 as a Cloning Vector

Phage M13 is a single-stranded coliphage that goes through a double-stranded replicative

phase in *Escherichia coli,* producing about 300 copies per cell. The phage does not lyse the cell but continuously extrudes phage particles containing single-stranded DNA into the medium. The replicating phage, however, does slow down the growth of the infected cells, producing turbid plaques.

MESSING has adapted this phage successfully for genetic engineering experiments such as DNA sequencing and site-specific mutagenesis [28]. Several variants have been constructed and are available commercially. Introduction of the *lacZ* gene and its promoter into a nonessential region of the phage is extremely useful. The coding sequence of *lacZ* is interrupted by a polylinker (a synthetic DNA fragment that contains sites for several different restriction enzymes). Any one of these sites may be used to clone either cDNA or a genomic fragment. The ligated replicative form is then transfected into a *lac*$^-$ *E. coli* host, and the recombinant colonies are picked as clear plaques on X-gal medium. The background colonies appear as blue plaques because the *lacZ* function is not interrupted. The M13 vectors are indispensable today for the Sanger method of DNA sequencing which utilizes single-stranded templates (see Section 3.3) and oligomer-directed site-specific mutagenesis.

2.2. Synthesis of cDNA

The synthesis of cDNA is used for cloning when the primary aim is to obtain the protein product of the gene.

Preparation of cDNA. The enzyme reverse transcriptase (E.C. 2.7.7.49) is a kind of DNA polymerase found only in retroviruses (see → Enzymes, Chap. 6.2.4.) [29]. It differs from other DNA polymerases by synthesizing DNA from an RNA, and not a DNA, template. Because most eukaryotic mRNA molecules contain a 3′-hydroxyl polyadenosine (polyA) tail, an oligodeoxythymidine (dT) primer is used to prime the reaction. The resultant structure is a DNA · RNA hybrid. The RNA strand can be destroyed with alkali, leaving a single-stranded cDNA copy of the original mRNA. The single-strand cDNA is apparently capable of self-priming due to formation of a transient hairpin loop at its 3′ end. A second polymerase reaction using either reverse transcriptase or DNA polymerase I completes the second strand synthesis. The hairpin and any other single-stranded regions are trimmed away by using the single-strand-specific nuclease S1, which results in a flush-ended duplex structure [30].

In a variation of this scheme, known as the Gübler procedure, RNaseH (endoribonuclease, E.C. 3.1.26.4) is used at the RNA · DNA hybrid stage (Fig. 5.) This nuclease creates nicks in a RNA · DNA molecule. These nicks are extended and filled in by using *Escherichia coli* DNA polymerase I, which has both a 3′ → 5′ exonuclease activity and a 5′ → 3′ polymerase activity. In the final step, T4 DNA polymerase is used to eliminate any persisting 3′ overhangs. This method gives a superior yield compared to the original method [31].

Figure 5. Scheme for cDNA synthesis according to the Gübler procedure
See text for explanation.

Insertion of cDNA into the Vector. Double-stranded cDNA may be inserted into the vector of choice. For insertion into *plasmids, cosmid, or M13 vectors,* synthetic oligomeric DNA fragments (linkers) that carry the recog-

nition site for a desired restriction enzyme are ligated to the ends of the cDNA. The resulting fragment is then cleaved and ligated into the vector cut with the specified restriction endonuclease.

For insertion into *plasmid vectors,* a homopolymer tailing reaction is used which employs the enzyme terminal deoxyribonucleotidyl transferase (E.C. 2.7.7.31) [32]. This enzyme catalyzes the addition of deoxynucleotides to the 3′ hydroxyl terminus of a DNA primer. In most cases, the plasmid pBR322 is cut at the *Pst*I site and tailed with oligodeoxyguanidine (dG), and the cDNA is tailed with oligodeoxycytidine (dC). When the cDNA is annealed to the linear plasmid backbone, the *Pst*I site is regenerated, providing a convenient means of excising the inserted DNA by using *Pst*I [33]. Alternatively, dA – dT tailing may be used. Because dA – dT polymers have a lower melting point than dC – dG polymers, the inserted DNA may be excised with S1 nuclease under partially denaturing conditions [34].

The *Okayama and Berg cloning system,* first described in 1982 [35], is becoming increasingly popular because it yields full-length or almost full-length cDNA clones with a very high efficiency. The main feature of this strategy is that the entire cDNA synthesis is carried out on the plasmid. The process is initiated by using a plasmid primer tailed with oligo(dT) to which the polyadenylated mRNA is annealed (Fig. 5). The cDNA is tailed with oligo(dC) and annealed to an oligo(dG)-tailed, plasmid-derived linker. All subsequent steps are essentially as described above. This procedure has also been adapted to a mammalian cloning vector pCD [36]. The mammalian system provides an added advantage in that the cloned cDNAs can be screened directly for expression, because the vector carries all the essential regulatory sequences such as promoters, splice signals, and polyA signals.

3. Methods for Screening and Identifying Recombinant Clones from a Library

3.1. Nucleic Acid Hybridization

Double-stranded DNA can be melted at high temperature (>90 °C) to yield two single strands, a process termed *denaturation.* Under suitable conditions these single strands reassociate to give the original double-stranded structure; this is termed *renaturation.* Renaturation can take place between any single-stranded nucleic acids as long as their nucleotide sequences are complementary, i.e., DNA – DNA, RNA – DNA, or RNA – RNA. This provides a sensitive method for detecting recombinant clones. Several quick and convenient hybridization methods have been devised for library screenings and detecting specific DNA or RNA sequences.

Plaque-Lift Hybridization. When screening phage libraries, the phage plaques obtained in agar plates can be lifted onto a nitrocellulose filter by simply placing the filter on the agar surface [37]. The filters are then treated to lyse the phage particles, and the released DNA is denatured and fixed. The filters can then be hybridized by using a radioactively labeled DNA or RNA probe under appropriate hybridization conditions. The positive plaques can be identified by autoradiography (Fig. 6). A plaque that gives a positive signal in the primary screen (Fig. 6 A) is isolated, and the putative recombinant phage derived from this plaque is used to infect a fresh *Escherichia coli* culture. The plaques are once again analyzed as described previously; in this second step, a severalfold increase in plaque purification occurs (Fig. 6 B). The process is repeated a third time with a single isolated plaque; in the third step, total purification is usually achieved (Fig. 6 C).

Colony Hybridization. In a process similar to plaque-lift hybridization, nitrocellulose replicas of crowded bacterial colonies may be made [38]. The filters are then treated with detergents such as sodium dodecyl sulfate to lyse the cells and release the cellular contents. The filters are baked to fix the nucleic acids, at which point they are ready for hybridization with the radioactively labeled probe. The positive colonies are evident on autoradiography and can be picked from the original master plate for further investigation.

Southern Blotting. Southern blots provide a means of localizing specific DNA fragments within a mixture [39]. The fragments are first

Figure 6. Three-step purification of a recombinant plaque by using plaque-lift hybridization and autoradiography for identification
Positive plaques are blackened (arrow) and their proportion increases in successive purification stages (A, B, and C). In the final step (C), all plaques give a positive signal, indicating a pure clonal preparation.

separated by gel electrophoresis. After denaturation, the DNA is transferred by passive diffusion to a nitrocellulose filter by placing the gel on the nitrocellulose sheet and then immobilized by baking the filter for 2 h at 65 – 80 °C in a vacuum oven. A radioactive DNA or RNA probe can be used to locate the band of interest. The technique is applied mainly to confirm the presence of a specific sequence in cloned DNA. It is also extremely useful for locating sequences in total eukaryotic DNA (Fig. 7).

Northern Blotting. Northern blots are usually applied after confirming the identity of a clone. The RNA, not DNA, isolated from the appropriate cell sources is electrophoresed and transferred to a nitrocellulose filter as described for Southern blotting [40]. Hybridization with the cloned DNA probe can yield useful information such as confirming the transcription of the cloned piece of DNA as well as the number of copies of RNA that are synthesized. This procedure may also be used to test various tissue sources for the presence of a particular RNA. By using appropriate probes, the start and stop sites of transcription and regions that are spliced out of RNA during RNA processing can also be identified [41].

Preparation of Radioactively Labeled Probes. Probes for nucleic acid hybridization are labeled primarily with radioactively tagged nucleotides. A double- or single-stranded DNA or RNA fragment may be labeled at the 5′ end by using a γ^{32}P-labeled ribonucleotide. Probes of very high sepecific activity can be prepared by using a technique called *nick translation* [42]. Here, nicks are produced in a double-stranded DNA fragment with DNase I and subsequently filled in with radioactively labeled nucleotide triphosphates by using DNA polymerase.

3.2. Immunodetection Techniques

Detection techniques based on immunochemical methods are extremely useful in screening expression libraries such as λgt11. The recombinant plaques are lifted onto nitrocellulose as described in Section 3.1. A specific antibody is used in the first step to bind to the recombinant protein. In the second step, this antibody reacts with a species-specific antibody that is either radioactively labeled or tagged with an indicator enzyme (e.g., alkaline phosphatase or horseradish peroxidase). In the former case, autoradiography is used to detect the positive clones; with the latter, the substrate gives a chromogenic response on reaction with the enzyme. A variation of this technique is popularly referred to as *Western blotting* [43]. Cellular extracts or mixtures of proteins are electrophoresed on a polyacrylamide gel and transferred by electroblotting techniques to a nitrocellulose sheet. Detection techniques are identical to those described for plaque-lift assays. The Western tech-

nique is extremely useful for identifying a specific protein in a mixture of proteins and also yields information on approximate protein size. It is used widely as an identification test in the course of expressing a protein.

Figure 7. Southern blotting
The amplification of human interleukin-4 (IL-4) is followed on increasing concentrations of methotrexate (see Section 4.3.1.3) by using a "nick-translated" radioactively labeled probe (see below)
a) Lambda DNA *Hin*dIII marker; b) Mouse fibroblast cell line (L cells) transfected with Hu IL-4 cDNA plasmid; c) "Unamplified" Chinese hamster ovary (CHO) cell line transfected with Hu IL-4 cDNA plasmid; d) – f) Sister clones of CHO cell line transfected with Hu IL-4 cDNA plasmid and selected on 500 nmol/L methotrexate for DNA amplification (see Section 4.3.1.3.). Arrow points to the band corresponding to the 1L-4 coding sequence.

3.3. Sequencing Techniques for DNA

The development of rapid DNA sequencing techniques has facilitated characterization of a cloned sequence. The DNA sequence reveals important features such as the location of the restriction sites and open reading frames which may be used to deduce the amino acid sequence of the protein. Sequencing of DNA is carried out either by the method of Maxam and Gilbert [44] or by the dideoxy method described by Sanger [45]. Several automated DNA sequencers are now available. Most of these use Sanger's dideoxy method of sequencing. An innovative approach employs fluorescent dyes to label the nucleotides, thus allowing direct readout of the gels [46].

Figure 8. Autoradiogram of a DNA sequencing gel run according to Sanger's dideoxy method
The gel is "read" as described in the text (Section 3.3). Part of the base sequence is shown.

The *Maxam and Gilbert method* is based on the random cleavage of a DNA fragment by chemicals that cleave specifically at A, G, C, or T residues. Each of these reactions is carried out separately, and the four mixtures are electrophoresed on adjacent lanes of a polyacrylamide gel. The resulting fragments are separated strictly on the basis of their size. Because the starting DNA fragment is radioactively la-

beled at the 5′ end, the fragments on the gel can be detected by autoradiography. The sequence is read by starting with the lowest band and moving upward in a serial fashion, identifying bases by the lanes into which they fall.

The *Sanger method* uses a chain-terminating dideoxynucleotide. Here, the reaction depends on enzymatic synthesis of a complementary copy of a single-stranded DNA template (hence, the importance of cloning into single-stranded phage vectors such as M13; see Section 2.1.4). The substrate contains a mixture of the four nucleotide triphosphates, one of which is radioactively labeled. The reaction is performed on four mixtures, each of which contains one of the four specific dideoxy nucleotides at concentrations calculated to yield random terminations. Reaction is initiated by addition of the Klenow fragment of DNA polymerase (see → Enzymes, Chap. 6.2.2.). The reaction mixtures are electrophoresed in parallel lanes, and the gel is read as described for the Maxam and Gilbert method (Fig. 8).

4. Expression of Recombinant Clones

The production of proteins from recombinant DNA (i.e., *expression*) is an important aspect of genetic engineering. *Escherichia coli* has been extremely useful in the expression of foreign proteins that do not require post-translational modification for activity [47], [48]. However, in the case of complex proteins, (e.g., blood factor VIII), or proteins requiring post-translational modification (e.g., glycosylation or phosphorylation) for bioactivity, alternatives must be sought because *E. coli* is not capable of carrying out this task. Other major problems associated with *E. coli* are instability of the foreign mRNA or protein. Also, although expression levels as high as 40 % of the total cellular protein are achievable, the "foreign" protein often forms large, insoluble aggregates called inclusion bodies. This presents the problem of denaturing and refolding the foreign protein in vitro. Therefore, research on gene expression in lower eukaryotes (e.g., yeast) and in mammalian cells has gained prominence. The expression of foreign genes in a heterologous organism (i.e., from a different species) has drawn attention to the intermediate stages in expression of a protein, each of which may be rate limiting in the case of a foreign protein. Because the expression of high levels of a foreign protein is not essential to the functions of the host organism and may even be deleterious to its survival, a major area of research has been directed toward optimization of regulatory parameters for transcription, translation, and protein turnover.

Another aspect of heterologous gene expression concerns large-scale culture of the host organisms such as *E. coli, Bacillus subtilis,* fungi, and mammalian cell lines. Because the pharmaceutical industry already had extensive experience in large-scale fermentation of several antibiotic-producing bacteria, *E. coli* fermentations were standardized very quickly. Similarly, the brewery industry's experience with yeast was useful in dealing with recombinant yeasts. The greatest challenge was the scaleup of mammalian and plant cell lines. Many specialty houses mushroomed quickly to deal with this problem, which resulted in several ingenious technical innovations in this area. These include growth of cells on a synthetic microcarrier surface, gel entrapment of cells, and the growth of cells on solid matrices such as hollow fibers, collagen, or glass (→ Immobilized Biocatalysts) [49]. Most modern biotechnology companies can deal with large-scale growth of recombinant mammalian cell lines. For further details of biotechnological considerations, see → Biotechnology.

4.1. Heterologous Gene Expression in Prokaryotes

4.1.1. *Escherichia coli*

Escherichia coli is, by far, the most widely exploited prokaryote host for gene expression. The primary reason for this is that for decades *E. coli* has been the "workhorse" of microbial geneticists and, hence, its genetics and physiology are well-known. Early vector systems were based on the lambda bacteriophage and ColEI, an indigenous *E. coli* plasmid carrying the gene for the antibiotic colicin. Some of the earliest gene fragments to be cloned were well-studied *E. coli* promoters such as *lac* (lactose) [50], *trp* (tryptophan) [51], and λP_L [52].

Plasmid Vectors. Both inducible and constitutive plasmids with high copy numbers have been developed [53]. Constitutive high-copy plasmids arise from mutations in the control elements that regulate plasmid replication. Inducible high-copy mutants also have mutations in these elements but maintain a low copy number until they are induced. Inducible systems are generally preferred because the lower copy number of the uninduced plasmid allows more rapid cell growth. Both thermally and chemically inducible plasmid vectors have been used successfully in *Escherichia coli* [54]. On induction, these plasmids lose control over their replication and are termed runaway replication, high copy number mutants. The induced high copy number results in a dosage increase of the recombinant gene, generally with a concomitant increase in expression levels. However, the increase in expression level depends on the nature of the protein being expressed and may not be directly proportional to the copy number [55]. Most runaway-replication plasmids reach a copy number of 2000 per cell. Such intensive replicative activity tends to exhaust the cell's synthetic machinery and may even lead to plasmid instability. Also, in the case of inducible promoters such as *lac*UV5 and λP_L, it can very quickly dilute the repressor, making the system uncontrollable. Overexpression of certain genes such as tetracycline resistance can lead to plasmid instability. Plasmid stabilization technology has been developed and assures that plasmid loss is minimized to $10^{-4} - 10^{-6}$ cells per generation [56]. A plasmid stabilization system based on valine synthetase has also been developed [57]. Here, an *E. coli* host without valine synthetase activity is used, and its viability is assured by the presence of valine synthetase on the plasmid. This may be especially important when expression of a protein that is toxic to *E. coli* is desired because cells which have lost the plasmid possess a distinct advantage over plasmid-containing cells and could rapidly overgrow the culture.

Promoter Systems. A promoter is a conserved regulatory genetic sequence that is recognized by RNA polymerase for the initiation of mRNA transcription. The expression level of a heterologous protein must be directed by a host-specific promoter to achieve a high level of expression. One of the major efforts in genetic engineering has been to identify and construct strong promoters that have a high rate of transcriptional initiation.

A number of strong, inducible promoters have been developed based on the knowledge of endogenous *Escherichia coli* promoters such as *trp, lac, lpp* (lipoprotein promoter), and λP_L. In addition to natural promoters, several genetically engineered promoters have also been developed. An example is the *tac* promoter, which is a hybrid composed of the "−35 region" of the *trp* promoter and the "−10 region" of the *lac*UV5 promoter. It is stronger than either of the promoters from which it was constructed [58]. An extremely elegant, well-controlled expression system has also been developed in which the promoter and the gene to be expressed are maintained on separate plasmids [59]. Thermal induction of specific λ bacteriophage functions, that are maintained on the host chromosome results in specific recombination between the two plasmid species and expression of the recombinant gene. Bacteriophage T7 has also been exploited in several gene expression systems which rely on the fact that T7 RNA polymerase recognizes only T7 promoters and that *E. coli* RNA polymerase cannot recognize T7 promoters. Therefore, a gene cloned under the control of a T7 promoter is expressed only in the presence of T7 RNA polymerase. By placing the expression of T7 RNA polymerase under the control of an inducible *E. coli* promoter, the system can be turned on for heterologous gene expression. One such system relies on the presence of the T7 RNA polymerase gene which has been placed on the host cell chromosome [60].

Translational Efficiency. The efficiency with which a heterologous protein is translated from mRNA in *Escherichia coli* may be affected by parameters such as the ribosome binding site, the nucleotide sequences surrounding the ribosome binding site and the initiation codon [61], as well as codon usage within the gene [62]. In some cases, the secondary structure of the heterologous mRNA impedes efficient translation [63]. Addition of DNA sequences coding for several amino acids 3′ of the start codon increases the expression level of bovine growth hormone from less than 0.5 % to ca. 30 % of the total cell protein, with either a *trp* or an *lpp* promoter [64]. This effect is probably mediated

by an alteration in mRNA secondary structure that results in enhanced amenability to translation. Computer-assisted molecular modeling can be used to predict the secondary structure and introduce modifications that will yield better translation.

Secretory Systems. *Escherichia coli* secretory systems sequester the recombinant protein within the periplasmic space. The pINIII ompA system relies on the *lpp – lac* hybrid promoter along with the ompA signal peptide [65]. Another system is based on the *E. coli* alkaline phosphatase promoter and signal sequence [66]. The ompA signal peptide is derived from the gene encoding ompA (outer membrane protein A) in *E. coli.* The signal peptide is responsible for translocating the protein to the outer membrane. Both of these systems are inducible and have the following advantages:

1) Proteins are removed from the cytoplasm, thereby reducing toxic effects on the cell.
2) Exposure of the recombinant protein to cytoplasmic proteases is reduced, thus facilitating purification.
3) Proteins are obtained with their natural amino termini.

Escherichia coli does not usually secrete proteins into the medium. Attempts using hemolysin [67] and staphylococcal protein A amino terminal sequences [68], however, show promise and are being pursued in several laboratories.

Proteolytic Degradation and Fusion Proteins. One of the problems encountered during the expression of heterologous genes in *Escherichia coli* is the proteolysis of the foreign protein. With small proteins, this problem may be overcome by using a *lon*$^-$ or *htpR*$^-$ host background. The gene *lon* encodes the primary proteolytic activity, protease La, expressed during heat shock [69]; the *lon*$^-$ mutation inactivates this protease. The *htpR*$^-$ mutation results in inactivation of the repressor regulating the expression of the heat-shock operon. This operon codes for several proteases, including protease La. Because expression of a "foreign" protein can also trigger the heat-shock response, *lon* may play a major role in protein degradation. The *htpR* locus encodes a positive regulator of heat shock [70]. Therefore, an *htpR* mutation leads to nonexpression of heat-shock genes. The additive effect of *lon* and *htpR* suggests that other proteolytic enzymes may exist besides the protease La encoded by the *lon* gene.

The rate of proteolysis can also frequently be reduced if the recombinant protein is expressed as a *fusion protein.* This may be accomplished by using either an assembly of several copies of the gene of interest arranged one behind the other (*tandem copies*) [71] or an additional peptide sequence that can be cleaved after purification of the protein, e.g., collagen sequences [72]. Alkaline phosphatase fusion proteins have also been used to identify secretory mutants that show an increased level of expression of human growth hormone [73].

4.1.2. *Bacillus subtilis*

Bacillus subtilis, a gram-positive sporulating microorganism, has been explored extensively for the expression of foreign proteins. One of its most attractive features is the potential for secretion of foreign proteins into the culture medium. The surface of these organisms is enclosed by a simple, single cell-membrane system; they can thus secrete very high levels of some intrinsic enzymes. For example, up to 10 g/L of α-amylase (10 – 20 % of the total cellular protein) can be secreted by some industrial strains. Most of the proteins secreted into the growth medium by *B. subtilis* contain a *signal peptide* at the amino terminus. Translocation of the protein is guided by the signal peptide. The signal peptide is cleaved prior to release of the mature protein into the culture medium.

Another major advantage of *B. subtilis* is that it does not secrete any endotoxins. Furthermore, the fermentation industry has experience with this organism.

Plasmid Vectors. *Bacillus subtilis* itself has very few endogenous, naturally occurring plasmids; hence, most vectors have been derived from other gram-positive bacteria, mainly *Staphylococcus aureus.* These multicopy vectors replicate autonomously in *Bacillus* in a relatively stable manner. The most common vectors and plasmid progenitors available today are pUB110 [74], pC194 [75], and pE194 [76]; they

are all derived from *S. aureus.* The most important selection markers used are resistance genes to chloramphenicol, erythromycin, and kanamycin. Several bifunctional plasmids that are capable of replication in both *E. coli* and *B. subtilis* (e.g., pVH33 [77] and pBS42 [78]) are also available.

Promoter Systems. The α-amylase promoter–signal sequence is the most widely used regulatory sequence in *Bacillus subtilis.* Proteins such as staphylococcal protein A [79], human α-2-interferon [80], human γ-interferon, and *Escherichia coli* β-lactamase [81] have been expressed by using this system. Levels of secreted proteins range from 1 mg/L to 2 g/L. One of the major problems encountered, at least in the expression of human α-interferon, is sequestration of the precursor molecule as insoluble aggregates in the cytoplasm. Secretion of heterologous proteins hooked up with α-amylase signal is not always as efficient as that of the natural protein and is very dependent on the nature of the "foreign" protein. In addition to α-amylase, signal sequences from *B. amyloliquefaciens* alkaline protease and serine proteases [82] and *B. licheniformis* penicillinase [83] have also been used for the expression of heterologous proteins.

Extracellular Proteases. *Bacillus subtilis* secretes large quantities of extracellular proteases, especially during the onset of sporulation. This has been a major hurdle to expressing large quantities of heterologous proteins. To overcome this problem, attention has turned to obtaining host mutations that eliminate these proteases. Some mutants are now available, and their use has improved secretion levels of some heterologous proteins [82], [83].

4.2. Heterologous Gene Expression in Lower Eukaryotes (Fungi)

Fungi are a valuable source of commercially important natural products such as enzymes, vitamins, and amino acids. They are also widely used for fermentation processes. Both yeast and filamentous fungi (Fig. 9) have been exploited widely for these purposes. The vast experience of industry in the growth of these organisms has, in many cases, expedited industrial use of recombinant strains.

Figure 9. Photomicrographs of fungi used in genetic engineering
A) A commonly used laboratory strain of the unicellular yeast *Saccharomyces cerevisiae.* Notice the various stages of "budding" which indicate cell division; B) *Aspergillus nidulans,* a filamentous fungus currently being investigated as a host for production of heterologous proteins

4.2.1. Yeast (*Saccharomyces cerevisiae*)

Heterologous gene expression systems in yeast were pursued partly for the same reasons as the *Escherichia coli* systems. The genetics of the yeast *Saccharomyces cerevisiae,* chosen for this purpose, have been well studied. Yeast also offers the facility of a secreted product. The most appealing feature of the yeast system, however, is that it is eukaryotic; thus, yeast cells can splice mRNA precursors and carry out the posttranslational modifications (e.g., glycosylation, acetylation, proper folding) that are essential if a eukaryotic protein is to be fully functional.

Although a number of recombinant products have been expressed in yeast at high levels [84], expression levels are usually low com-

pared to those in *E. coli* or mammalian cells [85]. Another problem is the unfaithful cleavage of the heterologous product [86], which inevitably leads to severe problems in downstream protein purification. Although yeast was initially thought to be the ideal host, several promising features have fallen short of expectations; e.g., splicing functions are limited and do not follow the course generally observed in mammalian cells [87]. A major problem, especially in *Saccharomyces,* is hyperglycosylation of the heterologous product. Also, in certain cases, *Saccharomyces* has failed to glycosylate a given protein at its known glycosylation sites [86]. Yeast does not conform to mammalian systems in the manner in which it glycosylates a given protein [88]. Furthermore, the codon usage of yeast is very different from that of either *E. coli* or mammalian systems [89].

Plasmid Vectors. Two types of plasmid have been used widely for the expression of heterologous proteins in yeast: the 2-micron ($2\,\mu$) and the *ARS* plasmids.

2 μ Plasmid. The $2\,\mu$ plasmid is derived from an endogenous yeast plasmid that exists in the cell at a high copy number ranging from 50 to 100 [90]. By combining this plasmid with *Escherichia coli* plasmid pBR 322, several *shuttle vectors* have been constructed. These plasmids can replicate autonomously in both *E. coli* and yeast. They are extremely useful because they facilitate use of *E. coli* for all preliminary genetic manipulation, in addition to the ease of obtaining DNA from *E. coli.* The major disadvantage of using autonomously replicating plasmids is their inherent instability. This problem can be partly overcome by using 0^- strains of yeast which lack endogenous $2\,\mu$ plasmids. Such plasmids have been used successfully to produce large quantities of desired proteins.

ARS Plasmid. The *ARS* plasmids contain an *A*utonomously *R*eplicating *S*equence which was originally isolated from the yeast genome and confers autonomous replication function on plasmids in this organism [90]. Several *ARS* sequences have been isolated (e.g., *ARS1* [91], *ARS2* [92], and *ARS3* [93]). Sequence analysis indicates limited homology between the elements.

Like the $2\,\mu$ plasmids, the inherent problem with *ARS* plasmids is their relatively low stability, especially during mitotic growth [94]. This is generally attributed to competition for the initiation factors for DNA replication and their preferential segregation into the parent cell [95]. The *ARS* plasmids can be stabilized by introduction of centromeric DNA (*CEN*) [96] and become true minichromosomes. Mendelian segregation of the circular minichromosome then occurs during meiosis and confers plasmid stability in mitotic segregation. Several *CEN* elements have been identified and display significant homology [97]. The stability of *CEN* plasmids approaches, but does not equal, that of normal chromosomes.

Integrating Plasmids. Yeast can be transformed with linear plasmid DNA that is cleaved within a region showing homology with the DNA of the yeast genome. Plasmid integration is then targeted to the homologous genomic sequence [98]. Furthermore, multiple copies of the plasmid are found integrated into the yeast genome in a tandem array [99]. By using the *URA3* gene, this approach has been employed successfully to express high levels of heterologous proteins [100].

Linear Plasmids. Linear plasmids that are capable of autonomous replication in yeast are also called *artificial chromosomes.* They were initially constructed by flanking linear plasmids with terminal sequences of extrachromosomal ribosomal DNA (rDNA) from *Tetrahymena* [101]. Large linear plasmids that can exist in one or two copies per cell were found to be more stable than short linear plasmids or circular *ARS* and *CEN* plasmids. Their behavior during meiosis follows a strict Mendelian pattern of segregation.

Promoter Systems. A number of endogenous yeast promoters have been developed for the expression of heterologous proteins. The phosphoglycerate kinase (*PGK*) promoter and the 5′ coding region for PGK have been fused to the 5′ end of the human α-interferon gene. This inducible system has resulted in the expression of a PGK–α-interferon fusion protein as $1-2\,\%$ of the total cellular protein [84]. The *PGK* promoter has also been used to express human γ-interferon [86]. Another inducible promoter, derived from the acid phosphatase gene, has

been used in the expression of hepatitis B surface antigen [102]. The promoter derived from the yeast alcohol dehydrogenase gene (*ADH1*) has been used to express human α D-interferon [85]. Other useful promoters are the *GAL1* promoter, which is positively regulated by galactose [103], the extremely strong glyceraldehyde-3-phosphate dehydrogenase promoter [104], and the α-factor promoter [105].

Secretory Systems. A number of yeast secretory systems have been developed. One such system relies on the signal sequence derived from the yeast mating factor, mat-α, and has been used to express human epidermal growth factor [105]. Interestingly, this gene could not be expressed intracellularly. When fused to the α-factor signal sequence, the protein is secreted and correctly folded. The system, using a 2 μ-based plasmid, has been shown to process and secrete several proteins such as murine granulocyte – macrophage colony stimulating factor (GM-CSF) [106] and human interleukin-2 (IL-2) [107]. However, this system does not work with every protein. Smaller proteins such as growth factors seem to be more amenable to secretion than larger molecules. Other secretion signals such as *SUC2* and *Pho5* have also been employed to secrete heterologous proteins into the culture medium [88].

In most of the secretory systems, although a major proportion of the protein is directed into the secretory pathway, only a small fraction is secreted into the medium [85], [86], [88]. Obviously, rate-limiting steps exist. One way to overcome this problem is to isolate mutants with elevated levels of secretion–supersecreting mutants–which has been accomplished for chymotrypsin [88]. An encouraging aspect of the study is that these "supersecretory" mutants can be used with other expression – secretion systems, as well as for expressing heterologous proteins other than chymotrypsin [88].

4.2.2. Other Yeast Systems

The methanol utilization pathway of *Pichia pastoris* consists of genes that are responsive to methanol. The product of one of the genes, alcohol oxidase, makes up as much as 30 % of the cell's soluble protein. The regulatory sequence of this gene has been isolated and used for expression of heterologous proteins at high levels [108]. Expression can be controlled by switching carbon sources from glucose to methanol. Another appealing feature of *Pichia* is that, unlike *Saccharomyces,* it does not hyperglycosylate the proteins [108].

4.2.3. Filamentous Fungi

The direct appeal of filamentous fungi as hosts for heterologous gene expression derives from the fact that they secrete vast amounts of enzymes. Under optimal fermentation conditions, *Aspergillus niger* secretes up to 20 g/L of the enzyme glucoamylase from a single copy of the gene! By using the framework provided by yeast, the technology for gene expression in filamentous fungi is undergoing rapid development. Both *A. nidulans* (Fig. 9 B) and *Neurospora crassa* are eligible candidates because they are the most widely studied filamentous fungi.

Plasmid Systems. Attempts to isolate endogenous natural plasmids from *Aspergillus* and *Neurospora* have not been successful. The plasmid pDJB3 was the prototype for subsequent work [109]. It contains the ampicillin resistance gene and the origin of replication sequence from the *Escherichia coli* plasmid pBR325. Replication in filamentous fungi is made possible by the *ansl* sequence, which was isolated by following procedures employed for the *ARS* sequences of yeast. The *Pyr4* gene of *Neurospora* is used as a selection marker. However, several *Aspergillus* genes that match available mutants are now available and are being used in the development of vectors. The rate of transfer of DNA into the fungi (i.e., the transformation frequency) is high (5000 transformants/µg of DNA); most of the transformants are mitotically stable, indicating chromosomal integration.

Promoter Systems. A number of *Aspergillus* and *Neurospora* genes have been isolated, and their regulatory sequences are currently under investigation. The most sucessful application to date has been use of the glucoamylase promoter for the expression of bovine

chymosin in *A. nidulans* [110]. Glucoamylase promoter is induced by the presence of starch in the growth medium. The chymosin so produced was cleaved faithfully, with at least 90 % of the product being secreted efficiently. Although new, the filamentous fungi hold great promise as efficient secretors. However, a great deal of groundwork is still required, especially in the areas of vectorology and regulatory signals in order to exploit the full potential of this system.

4.3. Heterologous Gene Expression in Higher Eukaryotes

4.3.1. Mammalian Cells

Gene expression in mammalian cell cultures has an advantage over both the prokaryotic and the lower eukaryotic systems because it yields a product that most closely resembles the natural protein. Recombinant proteins expressed in mammalian cells are likely to be more properly glycosylated, assembled, and folded to yield functional proteins (post-translational modification). One of the major drawbacks of using mammalian cells as host organisms was considered to be the high cost involved in growing various cell lines. Extensive work has gone into developing cheaper culture media, and modern cell-culture technology is highly amenable to scaleup. For proteins such as erythropoietin, in which the activity is closely linked to glycosylation [111], expression in mammalian cells is the only available recourse. Also, *Escherichia coli* may not efficiently express extremely large molecules such as blood factor VIII or tissue plasminogen activator; therefore, these molecules are best expressed in mammalian cell lines. So far, almost every cell line used has shown faithful mRNA processing; i.e., the precursor mRNA is correctly spliced to yield the expected mRNA. When cDNAs with their signal sequences are cloned, faithful cleavage of the precursor protein and efficient secretion rates have been obtained.

The significance of glycosylation has still not been resolved. Glycosylation patterns appear to vary from one cell line to another. How critical is glycosylation of a protein to its functionality? What are the implications of altered glycosylation patterns? These questions have not yet been answered definitively. Many proteins that are glycosylated in their native state function equally well as unglycosylated forms expressed in *E. coli* [112], [113]. However, for some proteins such as erythropoietin, glycosylation is essential for bioactivity and alteration of the glycosylation pattern affects the range of bioactvity [114]. Furthermore, some cell lines cannot carry out all the different kinds of post-translational modifications. For example, several commonly used mammalian cell lines do not efficiently perform the γ-carboxylation step required by blood factor IX [115].

4.3.1.1. Vectors

Higher eukaryotes do not carry extrachromosomal (episomal) DNA molecules equivalent to bacterial plasmids. Most vectors are derived from eukaryotic DNA viruses or retroviruses.

Vectors Based on DNA Viruses. All eukaryotic vectors fall within two classes: integrating (intrachromosomal) or episomal (extrachromosomal).

Integrating Vectors. The most popular integrating vectors are derived from the *simian virus* SV40, a widely studied double-stranded DNA polyoma virus [116]. These shuttle vectors contain sequences from the bacterial plasmid pBR322 that allow replication and segregation in *Escherichia coli.* The SV40 sequences consist of a promoter unit, an intervening sequence, and a polyadenylation site. The cDNA to be expressed is cloned adjacent to the SV40 early promoter. A variation of this vector containing the gene for the SV40 T antigen (Tag) is also available [116]. The Tag is involved in SV40 DNA replication and promotes transient replication of vectors containing the SV40 origin. After transfection into COS-7 cells, the plasmid replicates rapidly. Due to the increased gene dosage, most heterologous proteins are expressed at easily detectable levels. This provides a quick method of screening recombinant clones within 72 h whereas 2 – 3 weeks are required with stable transformants that arise by random integration of the plasmid into the host genome. The COS-7 monkey cell line has the Tag integrated in its genome and is a popular cell line for transient transfections [117].

Episomal Vectors. The following are major advantages of an episomal vector:

1) Discrepancies or aberrations in expression of cloned genes resulting from random indiscriminate integration into the host genome can be avoided.
2) A standardized environment is available for comparison of related genes or their mutants.
3) A higher level of gene expression may be obtained due to the multicopy nature of the plasmid.

Of the episomal vectors, those based on the *bovine papilloma virus* (BPV) have been studied extensively. The BPV DNA is a circular duplex about 8 kb in length which is maintained episomally at about 100 copies per cell [118]. It can transform mouse, rat, and hamster cell lines and give rise to foci that can be visually scored [119]. A 69 % subgenomic fragment of BPV is sufficient to achieve transformation in the mouse fibroblast cell line C127 [120]. The plasmid is maintained in an episomal state.

Recombinant vectors have been constructed from this fragment and the plasmid pBR322 or pML-2, and are widely used for expression of heterologous genes [121]. If the vector containing the heterologous gene is maintained episomally, the copy number is generally low [121]. Although the BPV virus exists as an episome in its native state, the presence of a heterologous gene in the BPV vector may result in its integration into the host chromosome. The BPV vector has been used in conjunction with the metallothionein promoter to express biologically active dimeric human choriogonadotropin [122].

Bovine kidney virus (BKV) based vectors have also been employed to achieve high-level expression of heterologous genes in an episomal state [123].

The prospects for developing stable, nonintegrating plasmids may also receive an impetus from the discovery of indigenous episomal elements (*L factors*) in certain mammalian cell lines [124]. The L factors are circular duplex molecules that appear to have their own origins of replication. Whether they will maintain these characteristics after introduction of heterologous sequences remains to be seen.

Retroviral Vectors. A retrovirus has a RNA genome that acts as a template for DNA synthesis. The intermediate DNA is then used as a template for mRNA transcription. The demonstration that cloned retroviral DNA can produce infectious virus particles (virions) on transfection into cultured cells set the stage for their use as vectors [125]. Retroviruses have several advantages over DNA viruses. Integration of retroviral DNA into the host chromosome is obligatory for their reproduction and is carried out very efficiently. The long terminal repeat (LTRs) contain all the necessary information required in cis (i.e., on the same strand of the RNA genome) for transcription, replication, and integration [126]. The rest of the viral DNA can, therefore, be replaced by foreign DNA. By using a helper cell line to supply other viral functions in trans (i.e., from an independent genome), an infectious virion can be produced. In the case of *murine leukemia virus* (MLV) based vectors, two types of helper cell lines are available: those that produce a mixture of wild-type and recombinant virions, and Ψ^- mutants (the Ψ protein is required for the packaging of wild-type virion DNA) which produce only the recombinant virions. Retroviruses are capable of infecting various cell types; this fact has been exploited to introduce extraneous DNA sequences into bone marrow cells and embryonic cells. Retroviral vectors have been used to introduce cloned genes into cells both in culture and in vivo. Successful transfer of genes into normal bone marrow cells and their subsequent transplantation into recipient animals have been achieved [127]. Retroviruses are currently used to create transgenic animals by infecting preimplantation embryos [128]. With the recent understanding of tissue-specific expression of some mammalian promoters, the goal of tissue-specific expression (e.g., in milk and pancreas) has also been achieved [129], [130].

Most of the retroviral vectors are based on *Moloney murine sarcoma virus* (Mo-MSV) and *Moloney murine leukemia virus* (Mo-MLV). Many of the vectors such as MVGT [131] and M-MuLVneo [132] use the long terminal repeats for direct transcription of the cloned gene and the *gpt* and *neo* genes of *Escherichia coli* for selection. Others, such as MLVtK and MMuLV-SuTK-neo [133], carry additional promoters for expression of cloned genes. Presence of the SV40 origin of replication in the latter case allows amplification in monkey COS cells.

4.3.1.2. Promoters and Enhancers

A typical eukaryotic regulatory sequence contains a promoter and enhancer(s). The *promoter* guides the RNA polymerase to the correct initiation site for the eukaryotic messenger RNA. A typical eukaryotic promoter is about 100 base pairs (bp) long and consists of an AT-rich region designated the TATA box. The TATA box is generally preceded by one or more upstream regulatory elements (UPEs), which are about 12 bp in length and active in either direction. A well-known example of a UPE is the CCAAT box. The distance between the UPEs and the TATA box is critical for the rate of transcription.

An *enhancer* is a cis-acting element of DNA that stimulates transcription of adjacent genes from the promoter in either direction and over distances up to several kilobases. Viral enhancers were originally identified in SV40 and polyoma viruses and, subsequently, in a variety of others [134]. In addition, enhancer sequences have also been identified in normal cellular genes. Immunoglobulin enhancer sequences have been used to stimulate the transcription of nearby genes cloned on plasmids in lymphoid cells [135]. The ability of these sequences to stimulate transcription appears to be nonspecific because they increase the transcription of a number of different genes. The enhancer element has also been linked to several genes cloned in tandem, resulting in the high-level expression of all of them [136]. Both the enhancers and UPEs must apparently be recognized by one or more different soluble factors to elicit a full-fledged response. Viral enhancer sequences such as those of SV40 and adenovirus are active in most cells, and the level of their activity can be controlled by the availability of these factors. Some enhancers are inducible, for example, by heat shock [137]. The metallothionein enhancer is responsive to heavy metals [138], the β-interferon enhancer responds to viral induction [139], and elements in the long terminal repeat of Mo-MLV [140] and Mo-MSV [141] respond to steroids.

4.3.1.3. Chromosomal Gene Amplification

Plasmids containing sequences coding for dihydrofolate reductase (DHFR) are transfected and integrated into the chromosomes of *dhfr*$^-$ mutants of Chinese hamster ovary (CHO) cells [142]. After selection of *dhfr*$^+$ clones, these clones are placed under the selective pressure of the toxin methotrexate (a competitive inhibitor of DHFR), and the *dhfr* sequences undergo *amplification* (i.e., their copy number is increased several hundredfold). Almost always, the cDNA coding the recombinant protein of interest also undergoes amplification (see also Fig. 7). The resulting increase in gene dosage is accompanied by a simultaneous increase in expression level. This strategy has been employed successfully for high-level expression of recombinant proteins such as erythropoietin [143], blood factor IX [144], and human β-interferon [145].

4.3.2. Insect Systems

The baculovirus *Autographa californica* nuclear polyhedrosis virus (AcMNPCV) has been used to express heterologous genes in insect cells cultured from *Spodoptera frugiperda.* This virus is nonpathogenic to mammals and plants, and demonstrates a wide host range infecting at least 30 different Lepidoptera species. This system is helper-independent and uses the highly expressed promoter of the *A. californica* coat protein, polyhedrin, for expression of foreign genes. The level of expression obtained is consistently higher than that in *Escherichia coli,* yeast, or mammalian cells for a variety of genes [146]. Expression levels ranging from 1 to 500 mg/L have been observed. The system is still in a developmental phase, and several important issues remain unresolved. Polyhedrin expression varies depending on the cell lines infected and the composition of the media. For example, *S. frugiperda* cells accumulate high levels of polyhedrin, whereas the level produced by *Bombyx mori* cells is at the detection limit [146]. Expression of different genes in this system often varies widely. The effects of RNA structure, codon usage, and various control elements on gene expression are being investigated and may lead to improvements in the near future.

One of the major issues is the quality of the protein made by these systems. Insect cells appear to be extremely versatile in their ability to carry out post-translational processes such as secretion [147], localization in cellular organelles

[148] and at cell surfaces [149], proteolytic cleavage [147], phosphorylation [148], N- and O-linked glycosylation [147], [148], myristylation, and palmitylation [149]. Proteins such as human interleukin-2 [150], human β-interferon [147], and human α-interferon [151] have been successfully expressed in this system. Human β-interferon is glycosylated, the pre-β-interferon signal peptide is removed, and the mature protein is efficiently secreted. Human interleukin-2, however, is reported to be secreted in an unglycosylated form [152]. Glycosylation with carbohydrates such as sialic acid, galactose, and fucose may turn out to be inefficient in insect systems [146], especially in mosquito cell lines such as *Aedes aegypti* and *A. albopictus.* Efforts have also been directed at developing a modified baculovirus for direct introduction into live caterpillars. Expression levels are extremely high in this system, and it may prove to be a feasible economical alternative to cell culture [153].

4.3.3. Plant Systems

The availability of Ti (tumor-inducing) plasmid vectors opened up the possibility of studying genetic regulation at a molecular level in plants. Plant systems are adept at processing RNA, carrying out post-translational modification, and targeting proteins to their specific subcellular locations [154].

4.3.3.1. Plasmid Vectors

Development of efficient vectors for the introduction of DNA sequences into plants has been achieved primarily through the use of the Ti plasmid of the soil bacterium *Agrobacterium tumefaciens* [155]. This phytopathogen has evolved a sophisticated method of infecting its plant host cells in which a region of the Ti plasmid called T-DNA is integrated into the plant genome resulting in two specific physiological alterations: (1) diversion of carbon and nitrogen supplies for synthesis of derivatives of basic amino acids called opines that *A. tumefaciens* specifically catabolizes [156] and (2) proliferation of a tumor called crown gall [157]. The T region (T-DNA) of the plasmid contains the tumor-inducing genes [158], whereas the T-*vir* region is responsible for insertion of the plasmid DNA into the host genome [159]. Thus, any foreign DNA inserted in the T region is cotransferred to the plant cells.

Several approaches to introduce genes into plants have been pursued. Because *A. tumefaciens* cannot easily be transformed by naked DNA, alternative strategies had to be developed. Early methods involved insertion of DNA into a transposon such as Tn5 or Tn7 carried on a broad host-range plasmid in *Escherichia coli. Transposons* are mobile genetic elements that move from site to site in a bacterial, yeast, or mammalian genome. The selection of the introduced DNA segment was assured by a cumbersome, time-consuming "homogenotization" procedure [160]. Alternative vectors, such as the cointegrating and binary vectors, were developed to circumvent these problems.

An example of a cointegrating vector is the plasmid pMON200 which carries the pBR322 origin of replication and a selection marker, i.e., a Tn7-derived spectinomycin – streptomycin resistance gene [155]. A triparental mating procedure is used to transfer the new DNA into *A. tumefaciens.* Only the essential regions of T-DNA responsible for integration are retained; the T-DNA regions responsible for tumor formation are eliminated. *Agrobacterium tumefaciens* 3111-SE cells carrying the "disarmed" T-DNA plasmid pTi B6S3-SE are mixed with *E. coli* carrying modified pMN200 and *E. coli* carrying a helper plasmid pRK2013. The helper plasmid provides factors in *trans* that help to mobilize pMN200 into *A. tumefaciens.* The mixture is incubated overnight and then spread on a plate carrying a mixture of spectinomycin and streptomycin to select for the cointegrate plasmid that arises by homologous recombination with the Ti plasmid [161].

Cointegration into the Ti plasmid is an obligatory step for the replication of pMON200.

The binary vector system yields stable transformants [162], [163]. Both the T region and the *vir* region can be isolated from the Ti plasmid without loss of function. Therefore, the T-DNA can be manipulated in *E. coli* and then transformed into *A. tumefaciens* with a helper plasmid that carries the *vir* region. The presence of a complete T region is not essential for functioning of the binary vector system. In binary vectors such as pMON505 [164], the LIH region is re-

placed by the origin of replication derived from the broad host range plasmid pRK290. "Disarmed" T region DNA is equally efficient. Transfer into *Agrobacterium* cells is carried out either by transformation or by a triparental mating procedure using the mobilization helper plasmid as described above.

Gene transfer into plant cells can be carried out by infecting *A. tumefaciens* plant wounds with cultures of *A. tumefaciens* carrying recombinant Ti plasmids [165]. Direct DNA transfer into plant protoplasts can also be carried out by using transformation [166], electroporation [167], liposome fusion [168], microinjection [169], and leaf disk transfer [170] methods. The great advantage of gene transfer into plant protoplasts is that the transformed cells can be regenerated to give whole plants. This provides a powerful tool for carrying out genetic and molecular analysis of transgenic plants and their progeny.

The major advantage of the Ti system is its broad host range. It can induce tumors in most dicotyledonous species. In monocotyledonous plants, DNA transfer and integration take place, but no tumors are formed.

Naked DNA can be used to transform protoplasts derived from monocotyledons and dicotyledons. However, the DNA is scrambled, resulting in incomplete or rearranged copies [171]. Furthermore, plants cannot always be regenerated from protoplasts. Important issues still to be resolved include the effect of integration site on expression; the establishment of site-directed integration systems analogous to those available for yeast, and conversion of a Ti plasmid into an episomal vector by introduction of centromeres, plant autonomously replicating sequences, dominant selection markers, and regulatory promoter systems for expressing genes in specific cell or tissue types.

4.3.3.2. Plant Promoters

The most commonly used plant promoter is the nopaline synthase (*nos*) promoter [172]. Plant promoters possess the familiar TATA box found in most other eukaryotic promoters. Most plant genes placed under their normal promoters are fully active. Many of the promoters are specifically inducible; for example, a short, highly conserved, sequence of 33 base pairs appears to be responsible for the light inducibility of the gene encoding ribulose 1,5-bisphosphate carboxylase in the pea [173]. Similarly, signals that direct tissue-specific expression of the β-phaseolin gene of bean are localized to a 800-bp region at the 5′ end of the gene [174]. Many of these genetic regulatory pathways are being elucidated and offer the potential of using inducible systems to express cloned genes in a tissue-specific fashion.

5. Applications of Recombinant DNA Technology

5.1. Therapeutic Agents

The largest impact of the technological revolution produced by genetic engineering has been on the pharmaceutical industry. Almost every major pharmaceutical house was immediately attracted by the possibility of generating unlimited quantities of rare, valuable, therapeutically important proteins. This also led to a highly productive liaison between academia and industry. Distinguished scientists have joined forces with industrial firms to realize the commercialization of an academic research project in an industrial setting. However, while the replacement or improvement of traditional drug manufacture is attractive, it also requires standardization of cell growth and fermentation processes, as well as training of personnel to handle downstream processing and purification. Many of the companies concerned have invested substantial capital in this area. In addition to developing in-house capabilities, most of them also liaise with smaller biotechnology companies via contract research and product licenses. Although genetic engineering has simplified the manufacture of several established therapeutics such as insulin, growth hormone, serum albumin, and clotting factors, that were previously produced through purification from source tissues, it has also provided a host of new molecules that have substantial promise of being therapeutically important. In addition, development of safer vaccines derived from antigenic determinants such as surface proteins of pathogenic organisms has also become possible. The technology may also be

extended to enhance processes used for everyday pharmaceutical products such as vitamins, steroids, antibiotics, and other bioactive peptides.

Thus far (1988), four genetically engineered drugs have been approved for the United States market by the FDA, namely, human insulin, human growth hormone, human α-interferon, and tissue plasminogen activator.

Insulin derived from porcine or bovine sources was an already established product in the worldwide market for diabetes treatment. The cloned product was developed by Eli Lilly in collaboration with Genentech by using an *Escherichia coli* expression system [175]. The insulin produced by traditional methods is inexpensive and does not have immunogenic tolerance problems. However, submitting recombinant insulin for FDA approval provided industry with the experience needed in obtaining approval for other recombinant DNA products. For a detailed description of insulin, see → Peptide and Protein Hormones.

Interferon was discovered as an antiviral agent [176]. Leukocyte interferons constitute a multigene family, for detailed information see → Interferons [177]. The production of various interferons depends on the nature of infection; not all of them are induced at the same time. The first interferon to be cloned was human leukocyte interferon α-1 [178], followed almost immediately by human leukocyte interferon α-2. Interferon α-2 exhibited a more dramatic antiviral activity in human cells than interferon α-1 which was more potent in bovine cells [179]. Both Hoffman La Roche and Schering Plough proceeded with the expression of human interferon α-2 in *Escherichia coli.* In 1986, interferon was approved by the FDA for use against hairy cell leukemia in the United States and other countries such as the United Kingdom, the Federal Republic of Germany, France, Italy, and Canada. It is also approved for the treatment of Kaposi's sarcoma in the United States, Austria, Denmark, Switzerland, France, and the United Kingdom, as well as for multiple myeloma and condyloma acuminatum in Denmark, Portugal, Ireland, and Argentina.

The complexity of the interferon system was unknown at the time of its discovery. Therefore, cloning of the first interferon was hailed worldwide as a major breakthrough in medical science. Interferon was likened to penicillin as a broad-spectrum antiviral agent. Cloning of the first interferon led to the discovery that interferons are a finely tuned, complex, intricate network of molecules acting either in concert or independently to combat viral infections and modulate immune response. Besides hairy cell leukemia, human interferon α-2 may be therapeutically potent against renal cell carcinoma, warts, and multiple myelomas. Human infections caused by viruses, such as rhinovirus, herpes (eye and generalized infections), adenovirus (eye infections), papilloma virus, and hepatitis B virus, are also responsive to interferon treatment. Growing evidence indicates that this complex system may also protect the human body against certain bacterial and protozoan infections [180].

Human tissue plasminogen activator (t-PA) is a protein with a clear-cut function and is one of the most effective agents in dissolving blood clots. The protein is a multidomain serine protease that converts plasminogen to plasmin, which in turn lyses the fibrin network, thus helping to maintain hemostasis (→ Blood, Chap. 2.2.3.) [181]. It promises to be an effective therapeutic agent for thrombolysis in myocardial infarction, deep vein thrombosis, and similar indications. The cDNA for t-PA was cloned and expressed in CHO cells by Genentech using the DHFR amplification system (see Section 4.3.1.3.) [182]. Tissue plasminogen activator must be produced in mammalian cell lines because of its large size and extensive glycosylation. Clinical studies demonstrate decreased reocclusion rates and lower incidence of bleeding complications in patients treated with recombinant t-PA in comparison to other thrombolytic agents such as streptokinase [183]. Despite initial rejection, by late 1987 Genentech succeeded in gaining approval for t-PA in the United Kingdom, the United States, and Canada.

The systemic half-life of t-PA in humans is only 2–5 min [184]. The efficacious therapeutic dose in humans is, therefore, high and exceeds 100 mg [183]. This causes proteolysis of plasma proteins. A t-PA molecule with a longer half-life could overcome these problems and reduce the production cost per therapeutic dose. Several companies aimed to genetically engineering t-

PA to obtain a second-generation molecule with a longer half-life [185].

Human growth hormone was one of the earliest therapeutically important genes to be cloned [186]. Cloning allowed replacement of the tedious and cumbersome methodology involved in purifying this protein from pituitary gland. Genentech's application for the therapeutic use of human growth hormone was awarded by the FDA in 1986. The FDA also granted approval to Eli Lilly for a modified version of the hormone that lacked the N-terminal methionine residue. This modified hormone is claimed to reduce the antigenic problems posed by the Genentech product, which retains the N-terminal methionine. For a detailed description of growth hormone, see → Peptide and Protein Hormones.

Development of New Products. *Erythropoietin* is a hormone that stimulates precursor bone marrow cells to differentiate into red blood cells. Trials with recombinant erythropoietin indicate positive results for treatment of renal disease associated with anemia [187]. Furthermore, it may also be useful for treating sickle cell anemia, an inherited disorder of the red blood cell [188]. *Colony stimulating factors* are also generating strong interest in the treatment of several hematopoietic deficiencies [189]. Several of these have been cloned and are at various stages of development. Granulocyte colony stimulating factor (G-CSF) [190], granulocyte macrophage colony stimulating factor (GM-CSF) [191], macrophage colony stimulating factor (M-CSF or CSFI) [192], interleukin-3 (multi-CSF) [193], and interleukin-4 (B-cell stimulating factor 1) [194] are all being developed as products that could restore immunocompetence when used as an adjunct to chemotherapy. By the same criteria, these factors could prove to be extremely useful in treatment of systemic infections or burns and in bone marrow transplantation.

Interleukin-2 (IL-2) is also in advanced stages of testing, especially for cancer therapy in combination with lymphokine-activated killer cells or tumor-infiltrating lymphocytes. As with the interferons, the cloning of several of the cytokines has shed light on their role in the body's immune defense system. Interleukin-2, for example, appears to be the major inducer of γ-interferon. Interleukin-1, tumor necrosis factor, and γ-interferon are believed to play a role in several human diseases such as arthritis, diabetes, and atherosclerosis [195]. Therefore, interest exists in using the cloned products to set up screens for antagonist molecules.

Other products in the developmental stage are *growth factors* such as the platelet derived growth factor (PDGF), epidermal growth factor (EGF), and fibroblast growth factor (FGF) mainly in the areas of wound healing and angiogenesis. *Blood clotting factors,* such as tissue factor and factors VII, VIII, and IX, have been cloned and are in the developmental stage. Factor VIII is already being studied in clinical trials for inducing clotting in hemophiliacs [196]. *Hormones* such as thrombopoietin, follicle stimulating hormone [197], gonadotropin [198], and somatotropin [199] have been cloned and are currently being investigated (→ Peptide and Protein Hormones).

5.2. Vaccines

Control of deadly diseases such as smallpox, cholera, and polio can be attributed mainly to vaccines. For a detailed description of vaccines, see → Immunotherapy and Vaccines. Conventional methods of vaccine production have saved millions of lives. Despite the large market for vaccines, few companies have entered the field because they are intimidated by the immense legal costs. Genetic engineering, however, provides a safe alternative because it rules out vaccination by live or attenuated organisms and also offers the possibility of producing vaccines to control diseases that are beyond the scope of traditional methodology. Isolated gene products, especially surface antigens, can elicit an immune response from the body.

Several vaccines for use in humans are currently being investigated, some of the more important being those against hepatitis B, malaria, polio, herpes, gonorrhea, influenza, leprosy, and acquired immune deficiency syndrome (AIDS).

Hepatitis B Vaccine. The hepatitis B vaccine is the first genetically engineered vaccine to enter the U.S. market. The vaccine is produced by expressing the cloned hepatitis B virus surface antigen (HbsAg) in *Escherichia coli* and

yeast. The product physically and antigenically resembles the virus particles found in the serum of infected patients [200], [201]. Its efficacy as an immunization agent against hepatitis B infection was demonstrated in both chimpanzees [202] and humans [203].

Malaria Vaccine. The malaria vaccine is a prime example of what genetic engineering can accomplish where conventional approaches have failed. Because of the inherent antigenic diversity of the malaria parasite, the whole organism cannot be used as a source of vaccine. Cloning of some of the genes of this parasite has shown that some gene products may be invariant and, therefore, suitable candidates for a vaccine. An example of one such apparently invariant protein is the repeat sequence epitope from the circumsporozoite gene of *Plasmodium falciparum* [204]. A vaccine based on this sequence is currently undergoing clinical trials. If successful, it will replace or augment methods such as mosquito control and chemotherapy that are currently used to check the spread of this disease.

Acquired Immune Deficiency Syndrome. Acquired immune deficiency syndrome (AIDS) is caused by a retrovirus called the human immunodeficiency virus (HIV), which has been cloned and sequenced [205]. The virus is spread via body fluids, mostly by sexual intercourse or the use of contaminated syringes and needles among drug addicts. The alarming rate at which this fatal disease is spreading has caused great anxiety in the world health and medical community. AIDS has become the world's most deadly infectious disease, ranking fourth after ischemic heart disease, strokes and acute respiratory infections in terms of mortalities (2.28 million deaths worldwide in 1998).

A number of pharmaceutical and biotechnology firms are working closely with academic institutions to find methods to control this disease. A synthetic peptide fragment, encompassing the amino acid sequence from residues 735 to 752 of the viral envelope protein subunit gp41 was used to produce antibodies. The resulting antiserum reacted with the envelope subunit [206], indicating that viral envelope proteins are very immunogenic and may be used as a vaccine. A vaccine based on the recombinant version of the AIDS surface antigen protein gp160 produced in insect cells is already undergoing clinical trials [207]. The gp120 envelope protein of HIV-1 is also a prime target for use as a vaccine. Another approach is being followed by Smith Kline and French Laboratories and Genentech to develop an AIDS vaccine. Here, "soluble receptor" molecules are used that bind tightly to the virus, thus preventing its interaction with a lymphocyte or a brain cell [208].

Polio Vaccine. A novel approach has been used by Connaught Research Laboratories to develop a candidate polio vaccine [209]. An antigenic epitope for poliovirus type 3 was inserted into the 3′ end of the tobacco mosaic virus coat protein and expressed in *Escherichia coli.* Assembly of this protein was expected to produce a highly immunogenic, high molecular mass complex that carries several copies of the antigenic epitope. When injected into rats, this complex elicited a strong immune response that induced formation of neutralizing antibodies to poliovirus [209].

Other Vaccines. Production of vaccines via genetic engineering provides a method of obtaining proteins that undergo correct post-translational modification (e.g., glycosylation) by expressing them in mammalian cell lines. These modifications may be required for the protein to attain its native configuration. This is true in the case of the herpes simplex virus glycoprotein D, which when expressed in Chinese hamster ovary cells [210] can protect guinea pigs against genital viral infection.

Vaccinia virus vectors for polyvalent vaccines have also been developed [211]. Although this approach may allow one-shot immunization against several diseases, it is not without risk, because wide-scale use may elicit a severe response in patients with low immunocompetence. The safest vaccines are those that contain no DNA whatsoever, and the only way to achieve this is through synthetic and genetically engineered vaccines.

5.3. Genetically Altered Organisms

5.3.1. Transgenic Animals

Introduction of the human growth hormone gene under the control of metallothionein promoters

in mice was accomplished in 1983 [212]. This experiment caused a sensation because the mice inheriting the gene were much larger in size than control animals. Two methods are employed for introduction of foreign DNA into the fertilized mouse egg: (1) retroviral-mediated transfer and (2) direct microinjection into the male pronucleus of the fertilized egg. The DNA is integrated randomly and may form concatemers. Improved methods for targeting DNA to specific sites in the chromosome are still being perfected. Transgenic mice are widely used to study DNA sequences that mediate tissue- or cell-specific gene expression [137], [138]. In addition, they are employed as a routine tool to study oncogenes [213] and to set up animal models for genetically determined disease states [214].

The success achieved with transgenic mice promoted experiments with other animals such as fish [215], rabbits, sheep, and pigs [216], with a view to carrying out studies in improvement of livestock. One of the earliest experiments utilized human growth hormone in pigs. Despite high expression of the gene, no evidence of enhanced growth appeared [217]. Instead, the pigs developed arthritis-like symptoms. Growth hormone is normally produced in a highly regulated fashion by the pituitary gland. The development of pathological conditions was probably due to unregulated expression of the gene in all tissue types. When porcine growth hormone is expressed in a regulated fashion in transgenic pigs, their rate of growth is increased substantially. Furthermore, the meat is lean. Steps are being taken to commercialize breeding lines of such transgenic pigs [218].

The fertility of Booroola merino sheep increased severalfold upon introduction of the fertility (F) gene into transgenic sheep [218].

The latest use of transgenic animals has been in the production of heterologous proteins in milk. Using promoters of genes coding for milk-specific proteins (e.g., β-lactoglobulin and whey acid protein), researchers have expressed blood factor IX [219] and t-PA [129] in the milk of transgenic sheep and mice, respectively. Sheep β-lactoglobulin has also been expressed in transgenic mice, which produced up to 23 mg/mL of β-lactoglobulin in their milk [219].

Transgenic animals may soon become an attractive alternative for the production of genetically engineered, biologically active proteins. Several regulatory issues would have to be resolved, but expression levels and the quality of the product may excel those achieved via conventional methods.

5.3.2. Transgenic Plants

The concept of manipulating plant genetics has direct appeal for the agricultural industry. It provides a tool for introducing specific genes to protect plants against potentially lethal agents such as herbicides, viruses, and insects. Other advantages include the improvement of crop yield and quality.

The development of plasmid vectors carrying selectable markers for tranformation of plant cells brought about a revolution in plant breeding. By using the soil bacterium *Agrobacterium tumefaciens* with its associated Ti plasmid as a vector (cf. Section 4.3.3.1.), several transgenic strains of plants were generated. Kanamycin resistance carried on the *A. tumefaciens* plasmid is inherited stably in progeny of transgenic plants [154]. The host range of the *A. tumefaciens* is quite large among the dicotyledonous species ranging from petunias [220] to pines (e.g., the Douglas fir [221]), deciduous species (e.g., poplar [222]), and cotton [223]. Transfer of single gene traits has met with considerable success. Transgenic tobacco plants that carried a mutant *aro A* gene from *Salmonella typhimurium* conferred tolerance to the herbicide glyphosate [224]. The *aro A* locus codes for 5-enolpyruvyl-3-phosphokimate synthetase which is inhibited by the herbicide glyphosate. The mutant enzyme is resistant to the herbicide. By engineering a *Streptomyces* acetylating enzyme gene into tobacco, tomato, and potato plants, resistance to the herbicide Basta has been achieved [220]. Acetylation of the herbicide renders it ineffective. Resistance to tobacco mosaic virus was achieved in tomato and tobacco plants that were engineered to carry tobacco mosaic virus coat protein [225]. The presence of the coat protein provides cross-protection against superinfecting viruses because it encapsidates (packages) the viral RNA and renders it noninfectious. Another route to achieving viral resistance has been through transformation of tobacco plants with a satellite RNA species derived from a benign strain of cucumber mosaic virus. The pres-

ence of this RNA protects the plant from virulent infection [226]. Resistance against several insect pests has been achieved by creation of transgenic plants carrying a gene encoding cowpea trypsin inhibitor [227]. Proteinase inhibitors defend plants by inhibiting the proteolytic activity of the pathogens; the pathogens require this activity for the breakdown of plant protein and thus for their nutrition.

Direct transfer of naked DNA into protoplasts has also been employed in plant species that do not fall within the host range of *A. tumefaciens* [173]. This method is used particularly for monocotyledonous species, including cereals, which constitute the most important group of plants providing nutritional needs in humans. Protoplast fusion [228], liposome-mediated DNA transfer [229], and electroporation [230] have been used to transform these plant cells. Problems concerning the successful regeneration of plants from protoplasts have been partially solved, at least in the case of rice [231]. Attempts to repeat this success with other cereals such as maize, wheat, and barley are under way.

Although transfer of single gene traits has been accomplished successfully, many desirable traits such as disease resistance, stress tolerance, and photosynthetic efficiency probably depend on the activity of several genes. Intensive effort must, therefore, be mounted to characterize these genes. The availability of vectors, improved methods of gene transfer, and improvement in plant regeneration techniques have opened the door to what may be a revolution in plant breeding.

5.4. Gene Therapy

Gene therapy is considered by many to be the ultimate frontier still to be conquered by recombinant DNA technology. Despite intense research, progress has been slow. Gene therapy, as currently envisaged, differs from creation of transgenic animals in that it involves somatic gene manipulation as opposed to germ line manipulation. Work thus far has been restricted to laboratory animals. Approaches used for gene transfer include retroviral-mediated transfer [232], microinjection [233], electroporation [234], uptake of DNA precipitated by calcium phosphate [233], and homologous recombination [235]. The most popular of these methods is retroviral transfer. Concern exists over the use of retroviral vectors, and they must be shown not to pose a cancer hazard as a result of either recombination events or random insertion into (and activation of) oncogenes.

Hemopoietic stem cells have been the favorite candidates for gene transfer experiments. After retroviral transduction, the cells are transplanted into mice that have been lethally irradiated to eliminate existing stem cells. Expression of the introduced gene is checked four to six months later to allow for differentiation of stem cells [236]. Another method utilizes cultured murine fibroblasts; the cells are transfected with the desired DNA and implanted at several anatomical sites [237]. Expression of the gene of interest can potentially be regulated, depending on the site of implantation. This type of implantation has been termed "transkaryotic implantation."

Most of the early experiments used the retroviral LTRs for expression of the foreign DNA. The major problem has been low expression in the reconstituted cells. The LTR-based expression seems to be irreversibly blocked, especially in bone marrow cells. A breakthrough has been achieved [238]. A retroviral vector carrying the β-globin gene under the control of its natural promoter was transfected into hemopoietic stem cells. Measurable quantities of β-globin were found in all mice that had undergone bone marrow transplantation. These results illustrate the importance of the choice of promoters to achieve tissue-specific expression.

The aim of the above studies is to provide basic knowledge so that experimentation can be extended to humans. The most obvious candidates for gene therapy in humans are genetic hemoglobin disorders, the best known and most commonly inherited human diseases. Other candidates are diseases caused by inborn errors of metabolism such as the Lesch – Nyhan syndrome, which is due to a deficiency of hypoxanthine phosphoribosyltransferase, and severe combined immune deficiency syndrome, which is caused by defective production of adenosine deaminase.

Gene therapy is still viewed with skepticism and concern by the public. The FDA and the NIH Recombinant DNA Advisory Committee intend to scrutinize all gene therapy proposals closely

prior to approval [239]. However, the following criteria proposed by MULLIGAN may help researchers choose a disease suitable for gene therapy [240]:

1) The disease must be life-threatening and incurable.
2) The normal counterpart of the defective gene must be isolatable.
3) The organ or tissue responsible for disease-related pathophysiology must be identified.
4) Introduction of corrective sequences into a significant fraction of the affected system should be achievable.
5) The gene must be adequately expressed.

Although, in theory gene therapy should work, this goal has not been achieved in reality. The greatest detriments to progress have been inadequate expression levels, an inability to infect large numbers of cells, and a lack of methods for identifying the derived cell population in a mixed population of cells.

5.5. Diagnostics

One of the offshoots of streamlining DNA hybridization techniques is the establishment of diagnostics based on DNA probe technology. By using the exquisite specificity with which complementary sequences on single-stranded DNA or RNA find each other, cloned gene fragments are employed to detect infectious agents, hereditary markers, oncogenes, and antibiotic resistance genes. Currently, efforts are focused on replacing labor-intensive, time-consuming DNA hybridization methods with simpler and faster techniques. This is essential for successful commercialization of this technology, especially if it is to compete favorably with the immunodiagnostic market. Several of the currently employed tests use radioactively labeled probes. One of the first assays to be marketed was the *Salmonella detection* assay that utilizes a radioactive probe [241]. Simplification of DNA immobilization techniques and proprietary reactions that accelerate hybridization have helped to reduce the time required for such assays. The FDA approved the first isotopic probe in 1987 for the diagnosis of legionnaires' disease by use of patient specimens [241].

Because the use of radioactive isotopes is a cause for concern, especially in clinical laboratories that handle thousands of samples, many companies are trying to find nonisotopic tags. Suitable alternatives include fluorophore-based tests and enzymes linked to the probe either directly or via a biotin – avidin complex. The fluorophore-based tests are best suited to automation; inexpensive, easy-to-use fluorometers are being developed. Enzyme-based assays use dye conversion for detection, and these can be read on colorimeter or spectrophotometer. The low sensitivity of the nonisotopic methods presents a severe problem in that assay time is prolonged because the samples often require further culturing. Cetus has developed a selective DNA amplification technique called the polymerase chain reaction (PCR) that can amplify given DNA samples a million times [242]. This method relies on the hybridization of an oligomeric primer to a single-stranded DNA molecule and the ability of the DNA polymerase to complete the synthesis of the second strand. The double-stranded DNA is then denatured, and the whole process is repeated several times, resulting in a 200 000-fold amplification of the DNA sequence. This could overcome problems of low DNA content in samples and has been shown to be effective for detection of HIV-1 in DNA of peripheral blood mononuclear cells [243]. Several companies are involved in automating these assays.

Besides detecting infectious bacteria and viruses, DNA probe technology provides the means for diagnosing several inherited single gene disorders. Genetic screening by this method is based on analysis of restriction fragment length polymorphism (RFLP). Polymorphism in the DNA sequence is quite high (one in every 200 bp in the human genome). Because of the variance in DNA sequence, recognition sites for restriction endonucleases may also differ giving rise to altered patterns of restriction fragment lengths. Distinctive RFLP patterns can be linked to several genetic diseases such as thalassemia [244] or insulin [245] and growth hormone disorders [246]. The DNA from the patient's blood is digested with a specific restriction endonuclease, and the RFLP pattern is obtained by hybridization with a marker gene. Because deletions or mutations within the gene can produce an altered RFLP pattern, this type of

analysis can be used to predict the inheritance of a disease. A number of RFLP markers associated with specific diseases such as cystic fibrosis, sickle cell anemia, Duchenne-Type muscular dystrophy, thalassemia, hemophilia, retinoblastoma, and Huntington's chorea have been identified [247]. Some of these tests are available commercially, but still expensive (cost ranging from $ 800 to $ 1500) and time-consuming (8 – 10 d). Tests are also available for Philadelphia chromosome, chronic myelogenous leukemia, and T- or B-cell cancers.

6. Regulatory and Safety Aspects

Following the recommendations drawn up after the Asilomar meeting [248], the National Institutes of Health (NIH) set up the Recombinant DNA Advisory Committee (NIH RAC) in 1976. This committee proposed several levels of biological containment for experiments involving gene manipulation [249], with rigorous containment procedures. In addition, Institutional Biosafety Committees (IBCs) were set up by pharmaceutical companies and academic institutions to govern the conduct of everyday recombinant DNA research. Today, most countries involved in recombinant DNA research have implemented nationally monitored programs to control research in genetic engineering. Experience has shown that most genetic engineering experiments pose no greater threat than does conventional microbiological research. Consequently, containment levels have been relaxed in recent years. "High-risk" experiments such as those involving cloning of toxins and lethal viral genomes into harmless organisms are still strictly regulated. A surge of activity occurred in the study of transgenic animals. Some work in this area has also necessitated establishment of rigorous codes to prevent these animal populations from entering the common gene pool. For instance, the creation of transgenic mice carrying the entire genome of the AIDS virus has caused concern [250]. As a result, stringent measures have been advocated to prevent accidental release of these animals.

Another issue discussed frequently is the use of recombinant products as therapeutic agents. The main concern here is the authenticity of the product. Many factors such as codon usage, glycosylation, post-translational modification, protein folding, and methionyl derivatives (heterologous proteins expressed cytoplasmically in *Escherichia coli* that retain the N-terminal methionine) can all change the functionality of a protein. Some changes may be apparent immediately, but others may escape notice because of methodological limitations of the assay used.

An additional problem is the homogeneity of the preparation. Rigorous control of purification schemes used in the isolation of a recombinant product is required. The final product should be free of contaminants such as proteolytic fragments, host pyrogens, and host nucleic acid, which can elicit an immune respone in patients [251]. This may be deleterious to the efficacy of the drug or the general health of the patient. Therefore, studies must determine whether the resultant antibodies are specific, neutralizing, or associated with hypersensitivity. The use of cell lines and transgenic animals that synthesize the desired protein as production hosts is proposed as a method of overcoming these problems. Despite these problems, a number of recombinant products such as insulin, α-interferon, human growth hormone, and t-PA have made their way into the market and are being used successfully.

The application of recombinant DNA technology in agriculture has created microbes that protect plants from natural threats such as frost and insect pests, as well as transgenic plants engineered to withstand harmful herbicides and viruses. Controversy over the release of such organisms into the environment has reached dramatic proportions. Of primary concern are the mixing of gene pools in the environment and the inadvertent introduction of such "hardy" characteristics as herbicide resistance into "weedy" plants, with disastrous consequences. The NIH guidelines deal with the issue of field testing and deliberate release of such organisms with great caution on a case-by-case basis. The Environmental Protection Agency also provides recommendations in this case. Field tests for plants are closely monitored to ensure that they are grown in a controlled, isolated environment to prevent cross-pollination or their permanent establishment.

The benefits of engineered organisms for agriculture, health, and environmental purposes are obvious. The enormous promise of this technology is bound to be realized in coming years.

As in the past, all new issues will have to be addressed with prudence and wisdom so that rational guidelines for conducting such research can be drawn up and the fears of the general public can be allayed.

7. Glossary of Special Terms

amplification: generally refers to an increase in the copy number of a gene (this can sometimes be induced by selection pressure, as in DHFR-based amplification)

copy DNA: DNA strand synthesized on an mRNA template by the enzyme reverse transcriptase

cosmid: hybrid vector composed of part phage and part plasmid

enhancer: DNA sequence that can increase transcriptional initiation, sometimes even at a considerable distance from the promoter

episome: usually a double-stranded circular DNA molecule that can exist extrachromosomally within a cell

expression: generally refers to the biosynthesis of a protein directed by cellular components (mRNA, tRNA, ribosomes, etc.)

fusion protein: generally refers to a recombinant protein expressed as part of a protein that is abundantly expressed in the host organism (e.g., lac, Trp)

library: cDNA or genomic DNA, is a population of chimeric DNA molecules representing the genomic content or the mRNA content of a specific cell

ligation: the process that involves in vitro joining of double-stranded DNA molecules by the enzyme T4 DNA ligase

operon: cluster of genes that encode a specific biosynthetic pathway or function (e.g., lactose, heat-shock, or tryptophan operon)

phage: bacterial virus (e.g., λ, M13, T4, T7)

plasmid: double-stranded circular DNA molecule that can exist extrachromosomally and replicate autonomously

promoter: conserved sequence that is recognized by the host-specific RNA polymerase to initiate mRNA synthesis

replicon: an extrachromosomal DNA or RNA molecule that can replicate independently of the genome (automous replication)

repressor: protein molecule that can bind to a specific conserved sequence, the operator sequence, in certain promoter systems to turn off transcription

restriction endonuclease: enzyme that recognizes a specific sequence and catalyzes the formation of cuts in double-stranded DNA; used as a tool in genetic engineering

retrovirus: RNA virus that uses a DNA intermediate for replication

selection marker: gene such as drug resistance or an auxotrophic requirement used to select for a plasmid in a particular host background

shuttle vector: plasmid that has the requisite DNA sequences to permit its existence in more than one host such as bacteria and mammalian cell lines

transfection: introduction of naked DNA, generally of viral origin, into a cell

transformation: introduction of naked DNA, generally of bacterial origin, into a cell

translation: step in protein biosynthesis that involves the transfer of information from mRNA into the synthesis of a protein

transposon: genetic element capable of moving from site to site within a genome

1. Introduction

Germanium [*7440-56-4*], Ge, atomic number 32, atomic mass 72.59, is a semiconducting element found in group 14 of the periodic table.

Germanium has five natural isotopes: ^{70}Ge (20.53 %), ^{72}Ge (27.43 %), ^{73}Ge (7.76 %), ^{74}Ge (36.54 %), and ^{76}Ge (7.76 %).

Germanium also has some radioactive isotopes with greatly different half-lifes, the isotope with the longest half-life being ^{68}Ge (287 days).

In 1871, MENDELEEV predicted the existence and the properties of an unknown element, ekasilicon, to be placed between silicon and tin in his periodic system of elements. In 1886, WINKLER isolated a new element from argyrodite, $4Ag_2S \cdot GeS_2$. This element, named germanium, showed properties remarkably close to those predicted by MENDELEEV.

Germanium found its first industrial application in 1947 with the development of the transistor. Until the early 1970 s, it was used extensively in the solid-state electronics industry, although it has been replaced almost entirely by the cheaper silicon.

The main use of metallic germanium currently is for infrared optics. Germanium tetrachloride is used in optical fiber production. Germanium dioxide is used mainly as a catalyst in the production of polyester and synthetic textile fiber.

The total consumption of germanium was estimated to be ca. 70 t of the element in 1986. The main producers of germanium end products are located in the United States, Belgium, France, Federal Republic of Germany, and Japan.

Germanium is considered as a strategic material by the United States government. The erection of a stockpile with a capacity of 30 t of Ge was decided in 1984. The first delivery began in 1987 and the capacity may be increased to 140 t.

2. Physical Properties

Although high-pressure polymorphs are known, germanium normally crystallizes in the diamond structure with comparatively weak covalent atomic bonding, yielding the typical hardness and brittleness, as well as the semiconductor behavior of this gray amphoteric metal.

The specific structure of the forbidden energy gap (band gap E_g), the binding forces between the germanium atoms, and their mass determine the major electron – photon and photon –phonon interactions in the crystal lattice, which result in a broad optical transmission range for infrared radiation. The fact that this range covers a main atmospheric transmittance window between 7 and 14 µm, coinciding with the spectral emittance peak of a blackbody at room temperature, has promoted the use of germanium as an infrared optical material. Germanium's high refractive index results not only in high optical power and little spherical aberration, but also in the need for antireflection coatings. These materials often occur as exotic contaminants in recycling operations. Germanium's thermal properties sensitize this brittle material to thermal shock; crucible design and seeding techniques must also cope with a 6.6 % volumetric expansion of germanium during solidification.

Due to the occurrence of a narrow band gap, most physical properties of germanium (e.g., resistivity) depend strongly on temperature as well as on minute concentrations of solutes. An updated and extensive compilation of the physical properties of germanium can be found in [1]; Table 1 summarizes typical room temperature values.

Table 1. Physical properties of germanium at room temperature

Property	Value
Mechanical	
Lattice parameter, nm	0.565790
mp, K	1210.4
Density, g/cm^3	5.3234
Microhardness (Vickers-ASTM E384), kg/mm^2	780

Linear thermal expansion, K^{-1}	5.9×10^{-6}

3. Chemical Properties [2], [3]

Elemental Germanium. Metallic germanium is stable in air. At temperatures above 400 °C in oxygen, a passivating oxide layer is formed. This layer is destroyed by water vapor.

Germanium resists concentrated hydrochloric and hydrofluoric acids even at their boiling points, but reacts slowly with hot sulfuric acid. The dissolution of germanium in nitric acid proceeds faster than in sulfuric acid. In alkaline media in the presence of an oxidizing agent, e.g., hydrogen peroxide, germanium dissolves rapidly, even at room temperature. Germanium reacts readily with halogens to form tetrahalides.

Germanium and silicon are totally miscible and form a continuous range of alloys. The system with tin has a eutectic.

Germanium Compounds. Germanium can have valences of two or four. The divalent compounds are less stable and oxidize easily to the tetravalent compounds, which are similar to their silicon analogs.

Germanium dioxide [*1310-53-8*], GeO_2 M_r 101.59. Some properties of germanium dioxide are listed in Table 2. It exists in two crystalline forms and one amorphous form, all of which are white powders. The hexagonal form is obtained when germanium tetrachloride is hydrolyzed with water. This reaction leads to a voluminous gel that continuously releases its water during drying. The transformation to the tetragonal form occurs only on heating at 300 – 900 °C in the presence of a catalyst (e.g., an alkali metal halide).

The amorphous form is obtained by rapid solidification of molten GeO_2 or by reaction of $GeCl_4$ or GeO with oxygen in the gas phase. Moisture catalyzes the transformation from the amorphous to the hexagonal form.

Germanium monoxide [*20619-16-3*], GeO, M_r 88.59, is obtained by the reaction of GeO_2 with reducing agents like germanium metal, iron, carbon, carbon monoxide, or hydrogen above 600 °C. Germanium monoxide sublimes above 710 °C, and this property is used in some industrial processes to recover germanium from slags or residues (fuming of Ge). Germanium monoxide is insoluble in water.

Table 2. Properties of germanium dioxide

Property	Structure		
	Hexagonal	Tetragonal	Amorphous

Germanium Halides. Of the germanium halides, only Germanium tetrachlorgermanium tetrachloride [*10038-98-8*] has practical applications. The properties of the tetravalent halides are listed in Table 3. ide is obtained by reaction of chlorine gas with germanium metal and of hydrochloric acid with GeO_2 or germanates. Germanium tetrachloride is soluble in carbon tetrachloride. Industrial practice takes advantage of the insolubility of $GeCl_4$ in concentrated HCl (>6M) to purify $GeCl_4$ from trace impurities such as As, Cu, and B by solvent extraction with HCl.

Germanium disulfide [*12025-34-2*], GeS_2, M_r 136.72, is obtained by the action of H_2S on acidic germanium solutions. Because GeS_2 is insoluble in acid media, this reaction is used industrially to obtain germanium concentrate.

Germanates are obtained in reactions at elevated temperature (800 – 1200 °C), in which glasses are produced from melts of GeO_2 and metal oxides or carbonates. The reactions also occur at room temperature in aqueous solution; e.g., sodium germanate [*12195-31-2*], $Na_3HGe_7O_{16}$, is formed by treatment of a NaOH solution of GeO_2 with sulfuric acid.

Germanides can be produced by melting other metals with germanium and freezing the melt, e.g., Mg_2Ge [*1310-52-7*]. Germanes (germanium hydrides) are evolved when germanides react with acids: monogermane [*7782-65-2*], GeH_4, digermane [*13818-89-8*], Ge_2H_6, and trigermane [*14691-44-2*], Ge_3H_8, can be separated by fractional distillation.

Organometallic Compounds. The organometallic compounds of germanium have few technical uses. Properties and methods of preparation have been extensively described [4].

Table 4. Germanium minerals

Name and composition	Ge content, wt %	Mining location
Stottite, $FeGe(OH)_6$	29	none
Schauerteite, $Ca_3Ge(SO_4)_2(OH)_6 \cdot 3\ H_2O$	14	none
Briarite, $Cu_2(Fe,Zn)GeS_4$	13 – 17	none
Germanite, $Cu_3(Ge,Fe)S_4$	5 – 10	Tsumeb, Namibia
Renierite, $(Cu,Fe,Ge,Zn,As)S$	6.3 – 7.7	Tsumeb, Namibia Kipushi, Zaire
Argyrodite, $4Ag_2S \cdot GeS_2$	1.8 – 6.9	Freiberg, Germany
Canfeldite, $4Ag_2S \cdot (Sn,Ge)S_2$	0.1	Bolivia

4. Resources and Raw Materials [5], [6]

The concentration of germanium in the earth's crust averages 6.7 ppm, which is comparable to the concentration of zinc or lead. Thus, germanium is not scarce, but it is widely dispersed so that only a few minerals have been isolated. The most important are listed in Table 4.

Germanium is present in the lattices of certain sulfides, such as sphalerite. The concentration of germanium in some germanium-rich deposits is given in Table 5.

Table 5. Germanium content of diverse deposits

Type	Location	Estimated Ge content, ppm
Zinc ∗	Gordonsville, Tennessee, United States	400
	Nanisivik, Baffin, Canada	230
	Saint Salvy, France	150
	Tsumeb, Namibia	250
	Lyon Lake, Ontario, Canada	200 – 250
	Salafosa, Italy	200
	Bleiberg, Austria	200
Copper	Apex, Utah, United States	640
Coal	Northumberland, United Kingdom	300

∗ Germanium concentration in zinc concentrate.

In the past, germanite (Tsumeb) and renierite (Kipushi) were the principal sources of germanium. Currently, germanium is recovered mainly from byproducts of the zinc industry.

The only mining operation specific for germanium (and Ga) is located at an old copper mine, the Apex, that has been reopened for this purpose.

At one time, germanium was recovered from the coal ash of electric power plants in England. This source of germanium vanished due to the decreased coal consumption for electric power production. The former Soviet Union, and probably China, still recover germanium from this source.

5. Production

The overall production processes can be divided into two steps: (1) production of germanium concentrate (primary production) and (2) production of germanium end products.

The first step varies depending on the raw materials processed and the chosen technology. Pyrometallurgical processes are based on the volatility of GeO and GeS. Hydrometallurgic processes are based on precipitation of germanium as its sulfide or hydroxide or with tannic acid [*1401-55-4*].

More recently, solvent extraction has been reported using hydroxyoximes (e.g., LIX63 [*6873-77-4*]), or oxime derivatives (e.g., Kelex 100 [*29171-27-5*], and LIX26 [*85746-33-4*]) [7–18]. Fixation of germanium on resin impregnated with amines has also been patented [19]. However, published information on all of these is scarce and not always reliable.

The second step relies on the volatility of $GeCl_4$ as the separation – purification step. Because the processes used by the diverse producers are quite similar, this step can be described with one flow sheet (see Fig. 6).

Figure 1. Production of a germanium concentrate: flow sheet of Bleiberger Bergwerks Union (BBU)
Location: Arnoldstein, Austria; Bleiberg mine. Estimated Ge capacity: 6 t/a.

5.1. Production of Germanium Concentrate

The flow sheets for the production of germanium concentrate from germanite and renierite as raw materials have been described [20].

5.1.1. Bleiberger Bergwerks Union

Bleiberger Bergwerks Union (BBU) processes the leach residues of its own zinc plant by a thermic process in a modified Waelz oven (Fig. 1). Germanium monoxide is sublimed at ca. 1200 °C. After the fumes are leached, germanium is precipitated with tannic acid [*1401-55-4*]. The germanium-free solution is recycled to the zinc plant and the germanium concentrate is sold as such.

The use of tannic acid leads to a relatively poor germanium concentrate. Care must be taken to avoid problems in the zinc electrolysis due to the recycling of unreacted tannic acid [21–23].

Figure 2. Production of a germanium concentrate: flow sheet of Jersey Minière Zinc (JMZ) and Metallurgie Hoboken-Overpelt (MHO)
Locations: JMZ at Clarksville, Tennessee, United States; Gordonsville mine. MHO at Olen, Belgium. Estimated Ge capacity: 65 t/a

5.1.2. Jersey Minière Zinc

Jersey Minière Zinc produces zinc from its mines in Gordonsville and Elmwood, Tennessee. Germanium is concentrated in the leach residue, which is dried and shipped to Metallurgie Hoboken-Overpelt (MHO), Belgium (Fig. 2) [24].

At the Olen plant in Belgium, the germanium residue is leached, and germanium is separated by solvent extraction. After elution in an alkaline medium, a germanium concentrate is precipitated by hydrolysis [25]. The use of solvent extraction technology enables MHO to produce very rich germanium concentrates, regardless of the concentration in the feed [8–13].

Figure 3. Production of a germanium concentrate: flow sheet of Musto Exploration.
Location: St. George, Utah, United States; Apex mine. Capacity: 18 t/a of Ge and 10 t/a of Ga.

5.1.3. Musto Exploration

The Ge – Ga concentrates from the company-owned Apex mine are leached in sulfuric acid with SO_2 to reduce trivalent iron (Fig. 3). After cementation with iron to remove copper, H_2S is added to give a first sulfide concentrate. Gallium is then separated by solvent extraction. The

germanium concentrate containing ca. 3 % germanium is upgraded to GeO_2 of 98 % purity before being sold to refiners. Exploitation started in 1985 [26].

5.1.4. Peñarroya

Concentrates of Zn – Pb and germanium matte from Pertusola (see Fig. 5) , a subsidiary of Peñarroya, are processed together by the Imperial Smelting Process. Germanium is collected in the zinc phase, which is further purified by distillation in New Jersey columns (Fig. 4). Germanium is then concentrated in a residue by volatilization of zinc. However, due to ecological problems, thermal processes for zinc are losing importance compared with hydrometallurgic processes.

Figure 4. Production of a germanium concentrate: flow sheet of Peñarroya
Location: Noyelles-Godault, France; Saint-Salvy mine. Capacity: GeO_2 – $GeCl_4$, 60 t/a; Ge metal, 30 t/a

5.1.5. Pertusola

The zinc concentrates of Salafosa are treated at the refinery of Crotone (Fig. 5). The leach and purification residues of the hydrometallurgic plant are thermally decomposed in a cubilot. Germanium is recovered in the Pb – Zn fumes, a small portion going into the matte phase, which is processed further by Peñarroya (Fig. 4). After releaching the fumes, a germanium concentrate containing 7 – 35 % germanium is produced.

Figure 5. Production of a germanium concentrate: flow sheet of Pertusola
Location: Crotone, Italy; Salafosa mine.

5.1.6. Other Primary Producers

The Metallgesellschaft (Germany) recovers ca. 10 t/a of germanium from the hydrometallurgical plant of Datteln. China exports ca. 4 t/a of germanium. The production of the former Soviet Union is mainly used internally (estimated 40 t/a of germanium). Cominco (British Columbia, Canada) is developing a project for 10 – 20 t/a of germanium.

Eagle Picher (Quapaw, Oklahoma, United States) processed the residues of its zinc smelter by fuming in a Waelz oven at 1250 °C. Be-

cause this source is not economical at current prices, Eagle Picher now supplies its refining unit (25 – 40 t/a of germanium capacity) with purchased germanium concentrates [27]. Preussag (15 t/a) and Otavi (5 t/a) (both Federal Republic of Germany) processed germanite from Tsumeb before depletion, but they now buy concentrate [5].

Figure 6. Flow sheet of the production of germanium metal from germanium concentrate

5.2. Production of Germanium from Germanium Concentrate

The transformation of a germanium concentrate (mostly GeO_2) or germanium metal scrap to germanium (Fig. 6) [28] begins with conversion to $GeCl_4$:

$$GeO_2 + 4\,HCl \rightarrow GeCl_4 + 2\,H_2O$$

$$Ge + 2\,Cl_2 \rightarrow GeCl_4$$

The reactions are run at the boiling point of $GeCl_4$ (83.2 °C) in concentrated HCl (6 M) to avoid hydrolysis. Even when only GeO_2 is processed, a chlorine atmosphere is used to oxidize the volatile $AsCl_3$ to nonvolatile H_3AsO_4.

The $GeCl_4$, containing As^{3+} as the major impurity, is purified by fractional distillation. Traces of As, Sb, Cu, and B are extracted by HCl (>6 M) saturated with chlorine. Other purification techniques have been reviewed [20].

The purified $GeCl_4$ is hydrolyzed with high-purity water,

$$GeCl_4 + 2\,H_2O \rightarrow GeO_2 + 4\,HCl$$

After filtration and thorough washing, the GeO_2 is dried.

The usual method of producing elemental germanium is hydrogen reduction [29] of germanium dioxide in electrically heated tubular furnaces at ca. 650 °C, yielding a gray metallic germanium sponge. In industry, graphite and/or quartz boats and furnace linings are used. Quartz boats must be sandblasted and/or coated to avoid sticking and breakage.

Care must be taken to keep the temperature below 700 °C during reduction to avoid generation of volatile germanium monoxide. Adequate processing limits the germanium loss to less than 0.1 wt %.

As a result of the very stringent purity requirements, reduction processes [2] using carbon, flux electrolysis, or the direct reaction of germanium tetrachloride with zinc have lost industrial importance. The reaction of $GeCl_4$ with H_2 can be used to grow epitaxial germanium layers [30], but bulk germanium production is hampered by low metal yield and overall energy yield.

After complete reduction, the temperature is raised above the melting point (937 °C), and a polycrystalline germanium bar is solidified from one end to the other. Due to the different solubilities of the impurities in the liquid and solid

phases, the impurities concentrate by segregation [31] in the first or the last melt fraction to solidify. Hydrogen is highly soluble in molten germanium; therefore, to avoid porosity and blow holes, the crystallization speed must be limited to a few centimeters per hour.

5.3. Purification

To obtain semiconductor-grade germanium, the material must be further purified by zone refining [32], [33], under hydrogen, nitrogen, or another controlled atmosphere. Due to the low surface tension and high density of molten germanium, a crucible-free float zone-refining process never matured [34] (→ Crystal Growth, Chap. 6.4.). High-purity germanium is obtained by repeated passage of crude germanium through the zone-refining crucible. The number of efficient zone-refining passes which can be carried out in a single crucible is limited by the partition coefficient of the impurities between germanium and the crucible material. Eventually, an equilibrium between the concentration of impurities in the melt and in the crucible is reached. For this reason, a cyclic batch process, in which the zone refining is continued in a new crucible, is unavoidable if high-purity germanium is to be obtained. Between the successive refining steps, the less pure metal parts are mechanically cut away and recycled. A suitable etching technique [35] is required to clean and prepare the load as well as the crucible for the next refining step. Grain boundaries and other crystallographic imperfections (dislocations, vacancies, etc.) act as precipitation sites for impurities, impeding the ultrapurification.

Ultimate purity levels can therefore be obtained (and measured) only in single crystals grown in the most aseptic, dust-free environment. The physics and chemistry of ultrapurification of germanium have been discussed [36–38].

5.4. Transformation Processes

For most applications, the germanium must be processed further into a suitable size and crystallographic perfection and doped within a narrow range (e.g., 1–8 ppb) with a definite impurity (usually a group 13 or group 15 element) to yield the specified electrooptical properties.

Two techniques are available for this transformation: (1) the *Bridgman process* [39] which entails horizontal or vertical, possibly seeded, directional solidification in a graphite crucible, often improperly called casting, and (2) the *Czochralski process* [40], by which a crystal seed is dipped into a germanium melt and allowed to grow by suitable control of pull speed and heat balance (→ Crystal Growth, Chap. 6.). The second process yields the most perfect material, e.g., dislocation-free single crystals. The fundamental physicochemical background of crystal-growth processes was reviewed [41–43]. Modern equipment handles up to 150 kg germanium loads and allows growth of single crystals up to 300 mm in diameter in a typical 48 h cycle.

Germanium crystals are ground, sliced, and milled with high precision microcomputer-controlled, diamond-tooled machines into the desired geometrical shape. This operation generates huge and costly amounts of scrap fines which have to be recycled. The brittleness of germanium and the need to preserve a near-perfect, strain-free crystal lattice do not allow germanium forging; segregation of the indispensable dopants hinders precision casting.

6. Environmental Protection

In the primary production of germanium, environmental problems are not specific to germanium, but are those of the zinc industry (e.g., SO_2 emission, cadmium pollution).

When solvent extraction units are used (see Section 5.1), special attention must be paid to fire protection and cleaning of the off-gas. The off-gas of $GeCl_4$ production must be scrubbed with alkaline solution to destroy HCl and chlorine. Monitoring the hydrogen content in the air avoids any risk of explosion in the reduction section.

7. Quality Specifications

Major impurities (<10 ppm) in $GeCl_4$ are O, C, and H, all detectable by infrared spectrometry.

The concentration of all metallic impurities can be depressed to or below their detection limits (typically <5 ppb). Process-induced impurities in GeO_2 are H_2O (<3000 ppm, ASTM F5-60) and Cl (<300 ppm, turbidimetry). Often, C, F, and S are detected at ppm levels (conductimetry); all other elements are at or below their detection limit (<10 ppb).

Density (ASTM B 417-76, B 527-70) and grain size (ASTM B 330-76) obviously influence reduction kinetics, but the contamination risks inherent to all high-temperature processes suggest the use of all-quartz furnaces and synthetic quartz boats with palladium-diffused H_2 for the assessment of electronic grade GeO_2 by reduction (ASTM F 27-83).

The most commonly used characterization techniques for germanium metal are those that determine the electrical properties of semiconductors: e.g., transport properties (ASTM F 43-78, F 76-73, F 42-77) and crystallographic perfection (ASTM F 389-76). For evaluation of the optical quality of germanium, a number of routine spectroscopic and specialized interferometric techniques exist [44]. All of these methods are, however, sensitive to the surface preparation (polishing) of the sample. Since many of the optical and electronic properties of germanium are linked to one another [45], [46], the electronic properties, which can be more accurately and reliably measured, can be used to define the optical properties. Thus, for example, standard optical grade germanium is specified as *n*-type germanium with resistivity 5 – 40 Ωcm.

To determine the chemical nature and concentration of electrically active impurities, three sensitive (10^{-5} ppb) techniques are used: deep level transient spectroscopy (DLTS) [47], far infrared transmission (FIRT) [48] (Fig. 7), and photothermal ionization spectroscopy (PTIS) [49].

Impurity, ppb	"As reduced"	Refined
P	1.5	0.36
As	0.77	0.005
Al	1.1	0.27
Ga	0.031	0.005

The major residual impurities in high purity germanium (H_2 < 100 ppb; C, Si, and O < 10 ppb) are process-induced and barely detectable by their lattice phonon absorption in the germanium matrix (ASTM F 120-75, F 122-74) or by autoradiospectrometry [50], [51]. The concentration of other impurities can be depressed below 10^{-3} ppb.

Figure 7. Purification by zone refining
a) 8K-FIRT spectra of germanium "as reduced" vs. b) after zone refining

8. Chemical Analysis

The analytical determination of germanium has been reviewed [52].

Germanium can be determined by photometry at 510 nm after complexation with phenylfluorone [*975-17-7*]. Atomic absorption spectroscopy at 261.1 nm is less sensitive than the previous method. X-Ray fluorescence enables determination down to 5×10^{-3} %. Polarographic methods such as differential pulse polarography and anodic stripping have been developed for the determination of germanium (and other impurities) in Zn electrolytes.

The determination of impurities in $GeCl_4$, GeO_2, and Ge can be achieved by graphite furnace atomic absorption spectroscopy (GFAAS) [53] or spark source mass spectroscopy [54].

9. Storage and Transportation

Germanium tetrachloride is classified as a dangerous corrosive liquid subject to international regulations (ADR/RID-IMDG-IATA) under UN 1760 Class 8 Group II. The combination of these with the very stringent purity requirements of the optical fiber manufacturers demands the use of expensive packaging (e.g., glass/teflon [*9002-84-0*], tantalum-coated steel [*7440-25-7*]).

Table 6. Germanium market in 1986 ∗

Application	Product	Consumption, t	Annual growth rate, %
Infrared optics	optical-grade Ge, shaped mono- and poly-crystalline blanks	35	15
Optical fibers	high-purity $GeCl_4$	13	10
Catalysis	GeO_2 (hexagonal or amorphous), $NaH_3Ge_2O_6$	13	5
Electronics, optoelectronics	doped Ge single-crystal slices	2	5
High-energy radiation detectors	high-purity Ge single crystal	1	5
Luminescence	GeO_2	1	
Medical, alloys, and glasses	GeO_2, Ge pellets, and powders	5	5
	Total	70	11

∗ Excluding Eastern-bloc countries

The packaging should preserve the purity of the GeO_2 during transportation and storage. For relatively short storage, a hermetically sealed high-density polyethylene bottle is satisfactory. The quality degradation during longer storage is linked to diffusion of impurities through or deterioration of the polyethylene. In this case the use of fluorinated plastic foil or coating is advisable.

Germanium metal oxidizes slowly in air; therefore, its packaging should primarily take its brittleness into account.

10. Uses and Economic Aspects

Germanium is used in manufacturing a wide range of high-technology products. Table 6 summarizes these applications for the market economies with respect to market volume and trends, as well as the germanium compound used.

The use of germanium in *optical materials*, by far the most important today, represents ca. 50 % of the world consumption. Germanium itself is the primary high-quality lens and window material for thermal imaging in the 8 – 12 µm wavelength range. The materials trade-off for this application was reviewed [55]. The replacement of silicon by germanium as a cation in optical glasses [56] extends their transmittance toward longer wavelengths and increases the refractive index. The second property is used to confine the signal within the core of telecommunication optical fibers. The chemistry of germanium in fiber manufacture is discussed in [57]. With As, Sb, and Se, germanium forms nonoxide glasses [58], also used in IR optics (Fig. 8), and whose photosensitivity yields high-resolution photoresists [59].

Figure 8. Germanium for infrared optics: typical set of polished Ge blanks

The second major use of germanium is as *catalyst or cocatalyst* [60] in the production of polyesters (e.g., poly(ethylene terephthalate)) and synthetic textile fibers. The more expensive germanium catalysts are used when the final product must be a colorless fiber or plastic, e.g., photographic films.

Some germanates crystallize as typical *phosphors,* which reemit absorbed energy as visible radiation. Magnesium germanates and fluorogermanates, e.g., $Mg_{28}Ge_{10}O_{48}$ and $Mg_{56}Ge_{15}O_{66}F_{20}$, in which magnesium acts as activator, are used in lamps as a constituent of the fluorescent coating [61]. This is preferred to the cheaper arsenic-based phosphors, for which safety regulations are severe. Bismuth germanate [*12233-56-6*], $Bi_4Ge_3O_{12}$, is an in-

trinsic phosphor that is used as a single crystal in high-energy gamma-ray scintillator detectors [62]. The stopping power is extremely high because of the high atomic number of bismuth.

The remaining interest for germanium in electronics is based on the advantageous mobility characteristics of charge carriers in this material. Typical applications are high-power devices with low energy loss and photodetectors [63]. The most demanding photodetector application involves *gamma-ray spectroscopy detectors* [64], for which germanium must be refined to an extremely low impurity level ($<10^{-3}$ ppb) and grown in nearly perfect single crystals. Recent progress in producing stable insulating layers on germanium [65], as well as its crystal lattice match ($\Delta a/a < 5\times10^{-3}$) with GaAs [*1303-00-0*] (epitaxy) offers new hope for germanium as an electronic material in integrated circuits.

Figure 9. Belgian producer price for electronic-grade germanium dioxide (June 30 values from *Metal Bulletin;* the Belgian franc is the usual currency for the quotation of GeO_2)

Another use of germanium, although limited virtually to Japan, is the industrial production of organogermanium compounds such as bis(carbamoylethylgermanium) sesquioxide [*27031-32-9*], $(GeCH_2CH_2CONH_2)_2O_3$, for medical applications [66]. The use of germanium in alloys, e.g., high-precision resistors, is minor. The geographic production – consumption pattern for 1986 is summarized in Table 7.

Table 7. Production – consumption pattern for Ge in 1986

Country	Production, t	Consumption, t
North America	29	35
Western Europe	36	18
Asia	5	17

In consideration of the large internal scrap recycling coefficient of most production lines (see Section 5.2), care should be taken in evaluating the apparent refining overcapacity of many producers.

Figure 9 illustrates the producer price evolution of electronic-grade GeO_2, largely determined by the refining costs of low-grade ores. The price of germanium metal in its various commercialized forms reflects the stringent requirements for purity and crystallographic perfection and, therefore, depends strongly on the specifications.

11. Toxicology and Occupational Health

Germanium and most germanium compounds are comparatively low in toxicity because of pharmacological inertness, diffusibility, and rapid excretion. However, some exceptions exist, the most important being germanium hydride (germane). Surprisingly, soluble germanium compounds are more toxic by oral than by parenteral uptake. Intoxication is characterized by a lack of gross tissue changes in animals dying from oral uptake of germanium. Industrial exposure is due mainly to germanium fumes and dusts generated during production.

Absorption, Metabolism, Excretion, and General Effects. Gastrointestinal absorption of germanium oxides and cationic salts is poor; in contrast, the absorption of germanates from small oral doses is ca. 75 % in 4 h and 96 % in 8 h [67]. Inhaled germanates are quickly absorbed from the lungs into the blood [68]. Elemental germanium and germanium dioxide are excreted mainly via the urine in rats, rabbits, and dogs [69]. No reports of Ge accumulation in human or animal tissues exist. High exposure levels of germanium salts disturb water balance leading to dehydration, hemoconcentration, decrease in blood pressure, and hypothermia [70], without showing gross tissue damage.

Acute Toxicity. The symptoms of acute germanium toxicity in animals are listlessness, marked hypothermia, diarrhea, cyanosis, edema, hemorrhage of the lungs, petechial hemorrhage in the wall of the small intestine, peritoneal efflusion, and edematous changes in heart muscle and in parenchymal cells of the liver and kidneys [71]. Germanium tetrafluoride and tetrachloride vapors irritate the eyes and mucous membranes of the respiratory tract [72]. Organic compounds, such as dimethylgermanium oxide [*1112-60-3*], are only slightly toxic to rats [73], whereas triethylgermanium acetate [*5061-27-8*] shows considerable toxicity [74]. Germanium metal dust (particle size 1.7 µm, concentration unknown) and GeO_2 (particle size 0.45 µm, concentration unknown) had no adverse effects on rats after inhalation for 1 h [68]. In rats and mice, the acute oral toxicity of alkylgermanium compounds ranged between 300 and 2870 mg/kg [74], [75]. Triethylgermanium acetate has an LD_{50} value (rat, oral) of 250 mg/kg body weight. The LD_{100} for germane (mouse, inhalation) is 610 mg/m^3 [67].

Germanium hydride, GeH_4, is a colorless, highly inflammable, toxic gas of low stability with a characteristic unpleasant odor. By inhalation, gaseous germanium hydride is the most toxic of germanium compounds. Inhalation of GeH_4 (70 mg/m^3 , minimally effective concentration) for 2 – 15 d caused nonspecific and nonpersistent changes in the nervous system, kidneys, and blood composition. Like other metal hydrides such as AsH_3, it shows hemolytic action in animals [76]. The lethal concentration in air is 150 ppm [77].

Chronic Toxicity. Symptoms of chronic germanium intoxication in experimental animals are mainly fatty degeneration of the liver and inhibition of growth: 1000 ppm neutralized GeO_2 (pH adjusted to 7) given in the diet of rats for 14 weeks depressed growth and caused 50 % mortality; 5 ppm germanium administered as germanates in the drinking water of rats and mice resulted in decreased life-span and mild fatty degeneration of the liver; 100 ppm GeO_2 in the drinking water for 4 weeks caused 50 % mortality without hematological or gross pathological changes.

Exposure Limits. A TLV for germane of 0.2 ppm, equivalent to 0.64 mg/m^3, was fixed by the TLV Committee of the American Conference of Governmental Industrial Hygienists in 1973 as an average limit of permissible exposure during an 8-h working day. No other TLVs for germanium or its compounds have been set in industrialized countries. Neither germanium nor its compounds are considered or suspected to exert a carcinogenic effect on humans or animals [78].

1. Definition and Historical Summary

Many molten materials do not crystallize to their parent crystalline phases once the thermodynamic melting temperature T_m is passed on cooling. Such melts easily supercool to a temperature far below T_m and congeal to solids without any attendant discontinuous changes in volume or entropy. These solids, which are isotropic in all their properties, are known as glass.

A common misconception is that all glass has the same composition. A variety of organic and inorganic materials can form glass, and most of those that do exhibit a moderately sharp transition into the glassy state from the liquid. Most common inorganic glass-forming systems are covalent compounds of the following elements:

Si, B, Ge, Sn, Pb;
P, As, Sb;
O, S, Se, Te.

Some elements (e.g., Se, Te, and S) also readily form glasses.

The canonical definition of the term glass is that by MOREY [54]: "Glass is an inorganic substance in a condition which is continuous with, and analogous to, the liquid state of that substance but which, as the result of a reversible change in viscosity during cooling, has attained so high a degree of viscosity as to be, for all practical purposes, rigid." Similarly, the ASTM defines glass as "an inorganic product of fusion that has cooled to a rigid condition without crystallizing."

Ease of glass formation is almost entirely a kinetic question. At no temperature is glass an equilibrium phase, although glasses hundreds of millions of years old are not uncommon in nature. The cooling rate required to form a glass varies with composition. Some melts (e.g., those of SiO_2 or B_2O_3) can form a glass at very slow rates of cooling, whereas mixed nitrates of potassium and calcium or sulfates of potassium and zinc, for instance, require rapid cooling from their normal melting temperature to form glass. Glassy metals have become quite common with the advent of rapid (splat) cooling techniques, the easiest to form having the approximate formula M_xL_y, where M is a transition metal; L is Si, P, C, B, or Ge; $x = 0.7 - 0.8$; and $y = 0.3 - 0.2$ (see → Metallic Glasses). Glasses can even be made from melts of metals such as iron and cobalt, but still higher quench rates are required than those for metal – metalloid glasses. Almost any inorganic melt can apparently be quenched into a glass with a sufficiently fast quenching rate.

Glass is not merely a supercooled liquid. The distinction between a supercooled liquid and a glass lies in the ability of structural elements in the former to rearrange themselves in accordance with the thermodynamic state of the system, whereas in the latter such rearrangement is not possible. This inhibition of rearrangement in glass is caused by the large increase in viscosity on cooling and gives rise to an endothermic effect on heating, which occurs at the glass transition temperature (i.e., the temperature above which structural elements in the glass are suffi-

ciently mobile to rearrange themselves according to their equilibrium configuration).

Literature on glass is abundant. The structure and content of this article are based on encyclopedia articles by GLIEMEROTH and MÜLLER [1] and by BOYD and THOMPSON [2]. Books on the scientific and manufacturing aspects of glass are the ones by BALTA and BALTA (1976) [3], DUNKEN (1981) [4], FRISCHAT (1975) [5], MCLELLAN and SHAND (1984) [6], PAUL (1982) [7], TRIER (1987) [8], TURKDOGAN (1983) [9], VOGEL (1985) [10], the Proceedings of the Conferences on Glass Problems edited by DRUMMOND (1986) [11], the Proceedings of the First International Conference on Advances in the Fusion of Glass edited by BICKFORD et al. [12] and the ones edited by BOYD and MCDOWELL (1986) [13], TOOLEY (1974) [14], and GIEGERICH and TRIER (1969) [15], [16]. The last book, though fairly old, is still the standard work on all glass-forming machines except for float glass; the primary difference between then and now being the optimization of economic performance of glass machines. A fairly extensive review of the spectroscopic properties of glasses is found in WONG and ANGELL (1976) [17]. A review of the spectroscopic techniques of choice for silicates can be found in the book edited by HAWTHORNE (1988) [18]. For the physics of silica the book edited by PANTELIDES (1978) is still the primary source [19]; for the chemistry of silicon the book by ILER (1979) [20] and the one edited by COREY et al. (1988) [21]. Among the literature on colors in glasses and minerals the books by WEYL (1961) [22], BURNS (1970) [23], BRAMFORD (1977) [24] and NASSAU (1983) [25] and the articles by FRITSCH and ROSSMAN (1987, 1988) [26] – [28] and SCHREURS and BRILL (1984) [29] should be consulted. The older literature on glasses is extensive and includes a review article by KAUZMANN (1948) [30] and UHLMANN (1983) [31], and books by UBBE-LOHDE (1965) [32] and RAWSON (1966) [33]. Pertinent classical references are the works by MOREY (1938) [34], TAMMAN (1925) [35], and WEYL and MARBOE (1962 –1964) [36]. Some sense of developments in the physics of amorphous materials, including spin glasses, and attempts to grasp their character in terms of localization and percolation can be gleaned from the thirty-first session on ill-condensed matter at Les Houches edited by BALIAN et al. (1978) [37]. Compilations of glass systems are found in the Phase Diagrams for Ceramists vol. I – V (1973 – 1985) [38] and in MAZURIN's books on phase diagrams (1973 – 1980) [39] and glass properties (1983 – 1987) [40]. Physical properties of glasses can be found in handbooks written by BANSAL and DOREMUS (1986) [41], CARMICHAEL (1982) [42], and CLARK (1966) [43]. BARIN and KNACKE (1973) [44], CHASE et al. (1985) [45], KUBACHEWSKI and EVANS (1958) [46], and ROBIE et al. (1979) [47] provide a wealth of thermodynamic data on silicate systems as does the definitive book on the structure of silicates by LIEBAU (1985) [48]. Phosphate mineralogy is covered in the book by NRIAGU and MOORE (1984) [49], its chemistry by VAN WAZER (1958) [50]. The Slag Atlas (1981) [51] gives a fairly extensive compilation of properties as well as an excellent synopsis of all property measurement techniques for glass systems of interest to the welding and metal industry. Two more books on glass are the ones edited by LEWIS (1981) [52] and MAZURIN (1989) [53].

The discoverer of glass manufacture will probably remain unknown. A source of inspiration may have been the abundant occurrence of glasses in nature. Obsidian, pumice (a natural foam glass), and tektites (glassy bodies probably of meteoric origin) are examples of naturally occurring glass. The earliest tektites worked by humans date from the Magdalenian period about 25 000 years ago. A synopsis of the developmental history of glass follows.

	b.c.
~2000	Glass was manufactured in the Caucasus.
~1500	Small artifacts were made in Atchana, Alalakh, and Tell al Rimah.
~1480	In what was probably the first occurrence of glass in Egypt (THUTMOSE III: Amarna period), alkali silicate glasses were colored with CaO, $Pb_2Sb_2O_7$, Al_2O_3; chromophores were Cu, Fe, and Mn. Asian glassmakers settled in Egypt.
~1450	Beautiful glass vases were made, inlaid with multicolored filigree glass.
~1200	Glass technology declined in Asia minor (Egypt, Mesopotamia).
~900	New glass centers started on the coast of Syria and in Mesopotamia.

~700 – 600 Glass making was established on Rhodes and Cyprus.
~630 Clay tablets in the Sardanapal library in Assyria describe use of tin as opacifier, production of alkali from plants, manufacture of frits and colorants.
~500 First Chinese glass artifacts date from this period.
~332 ALEXANDER THE GREAT supported expansion of Syrian technology.
~250 The blowpipe was discovered.

a.d.
Torso of an Aphrodite from Alexandria, cut from green glass, dates from this time.
First glass retorts were made for alchemists.
~70 Glassworks were constructed in Spain and France (glass manufacture was imported by the Romans from Egypt).
79 PLINY described the manufacture of glass.
100 Glass was manufactured in Köln.
100 Glass vessels were sold in Syrian shops in Sidon.
First vessels with relief were blown in molds.
300 Late Roman glass art from this time has been found in Christian catacombs.
~500 Syrian glass shops manufactured vessels with glass filament supports, head vessels with cut and etched patterns.
591 GREGORY OF TOURS mentioned glass church windows.
674 Glass windows were used in English churches.
~700 Window glass was manufactured in Syria by blowing, cutting, and sagging.
~700 Alkali content was lowered with respect to P_2O_5 (in bone ash).
~1000 Glass windows were made for Tegernsee cloister.
~1100 Small hand-held bend mirrors were introduced.
1180 Glass windows were first used in private English houses.
1202 Zenith of melt painting with copper containing colored glasses in the middle Rhine region.
~1300 Glass windows became more common in Europe.
1405 Silver engravings with glass layers were produced in Italy.
1453 Glass-making knowledge moved from Byzantium to Venice.
~1500 Clear glass was manufactured by glass shops in Murano, particularly wine glasses exported to Germany. Glass was decorated with pearls and buttons, painted, and gold plated.
~1500 Diamond was used to cut glass.
1507 ORLANDO GALLO improved Venetian glass technology. Mirrors were produced. Zenith of Venetian glass manufacture occurred.
~1550 Late blooming of Gothic glass painting appeared in Chartres and Paris.
1550 Glass thermometer was manufactured in Venice.
1590 Lenses were produced, presumably by ZACHARIAS JANSSEN.
1665 Large mirrors were made in France.
1680 JOHAN KUNKEL (1630 – 1702) manufactured ruby glass.
1688 Mirror glass was poured.
1697 Bohemian glass was produced in Venice.
1728 REAMUR observed devitrification.
1754 KLINGENSTJERNA disproved the thesis of NEWTON that refractive index is independent of wavelength.
1757 DELLOND constructed achromatic objective lenses.
1782 Industrial temperature measurement became possible with the Wedgwood pyrometer.
~1800 The first attempts were made to understand the constitution of glass.
1834 LENG interpreted devitrification as crystallization of silicic acid salts.
1845 Pocket watch industry started in a glass shop.
1857 The first glass oven with regenerative heating was developed.
1859 Semiautomatic bottle-blowing machine was used.
1867 Continuous tank was introduced.
1869 Silica was first drawn.
1879 The first blanks for incandescent lamps were made.
1900 Cylindrical blow machines were used for window manufacture.

1903 OWENS invented suction machine for bottle manufacture.
1904 The first neon light fixtures were made.
1906 FOURCAULT developed sheet-draw machine.
1909 A 1.52-m telescope mirror was manufactured for Mount Wilson observatory.
1915 Pyrex was introduced.
1917 Tank-drawn sheet glass appeared (Colburn machine).
1922 Single gob feeder was developed.
1925 Pittsburgh process for sheet glass was introduced.
1925 Draw process was used for tubes.
1926 Ribbon machine was developed for incandescent lamp bulb blanks.
1934 World's largest piece of glass was cast for 200-inch (5.08-m) telescope mirror on Mount Palomar, California.
1949 Centrifugal casting of television tubes began.
1950 First photosensitive glasses were made.
1967 Floating glass process was invented by PILKINGTON.
1970 Optical fibers were demonstrated with 20-dB/km loss.
1972 Vertical melting units were developed.
1978 Polychromatic glass was invented.
~1980 Development of fluoride-based glasses for optical fibers.
1983 Sol – gel extruded mullite fiber was invented.
1984 Pressing of elongated automobile headlights.

2. Structure of Glass

Methodology in condensed-matter physics and chemistry consists of identifying and relating the physical properties, structure, and constituent elements of a class of materials. For crystalline solids, the constituents and structure can be characterized readily. In glass, on the other hand, understanding of the structure consists almost exclusively of negative statements: no metric geometry, trivial space group, no Bloch states, no single ground state, no unique best structure. In addition, the topology of glass structure is almost amenable only to indirect experimental investigation.

It is not surprising in light of the undetermined nature of the amorphous state of glass that competing perceptions exist with regard to its character. The principal difficulty in distinguishing between models has been the small amount of energy associated with long-range ordering. For instance, the enthalpy of formation of quartz from silicon and oxygen at 298 K is − 860 kJ/mol; this is only 12 kJ/mol more negative than that for vitreous fused silica (− 848 kJ/mol). Only 1 % of the enthalpy of formation of quartz is therefore associated with long-range ordering. The two predominant structural models for glass are the microcrystallite and the random network hypotheses.

Microcrystallite Hypothesis. The microcrystallite "cybotactic group" hypothesis was constructed primarily to account for the discontinuous changes in the properties of glasses which can be correlated with similar discontinuities in the properties of associated crystalline phases. Proponents of this hypothesis were (with some rare exceptions such as STEWART and RANDALL [55], almost exclusively Russian, the first being FRANKENHEIM (1835)
and subsequently VON WEIMARN (1907)
who held that all matter in any state, be that gas, liquid, or solid is crystalline [56]. This work was followed up by LEBEDEFF (1921), who showed that vitreous amorphous silica varies considerably between 540 and 600° C in its double refraction, refractive index, and coefficient of expansion [57]. He inferred that this variation was due to a polymorphic transformation assumed to be connected with the low – high temperature transformation of quartz, which occurs at 575° C. He furthermore suggested that vitreous silica consists of an aggregate of very minute crystals with included quartz crystals that are probably not in a pure state, but in the form of a solid solution with other substances, hence accounting for the temperature range over which the polymorphic transition occurs. VALENKOV and PORAY-KOSHITZ (1936) analyzed the X-ray diffraction curves of glasses and concluded that the observed diffraction patterns [58] were produced by 0.75 – 2.5-nm crystallites that were connected to each other by an amorphous layer. These results made the microcrystallite postulate questionable because 2.5-nm crystallites do not represent long-range ordering in a crys-

tallographic sense. Refinement of diffraction experiments, particularly at small angles, has invalidated the original microcrystallite hypothesis. Recent electron microscopy results, on the other hand, indicate that multicomponent glasses can be chemically inhomogeneous, and contain microheterogeneities which could be taken to represent microcrystallites.

Random Network Hypothesis. The Zernike–Prins–Bernal–Fowler–Warren hypothesis [55] considers the liquid a system of atomic or ionic networks, designated as a random network. For glasses this implies a rigid system of continuous noncrystalline networks similar to those assumed to be present in the liquid. It remains open to debate whether there is one unique random network or perhaps more than ten thousand or what random really means in the context of liquid structures. The hypothesis was successful in providing qualitative explanations for the glass-forming tendency of simple glass-forming systems as being caused by a rapid increase in viscosity during cooling of the melt. In addition successful predictions could be made about potential glass-forming systems as well as rationalizations for most of property-composition relationships. Zachariasen (1933) postulated glass-forming tendencies for simple oxides based on random networks and the concomitant need for flexibility in linkages [59]. These postulates, in part already phrased by Goldschmidt (1926) for onide glasses [60], are the following:

1) Each oxygen atom can be linked to no more than two cations; the number of oxygen atoms around any one cation must be small, i.e., three or four; the oxygen polyhedra must share corners, not edges or faces, to form a three-dimensional network; at least three corners must be shared.
2) Network formers have a coordination number of 3 or 4 (Si, B, P, Ge, As, Be, etc.); network modifiers have coordination numbers greater than or equal to 6 (Na, K, Ca, Ba, etc.). Intermediate atoms with a variable coordination number between 4 and 6 (Li, Al, Mg, Zn, Pb, Nb, Ta, etc.) can function as network modifiers as well as network formers; the coordination change is a reflection of their amphoteric character, i.e., solubility in both inorganic acids and bases.

Additional refinements have been made to the random network theory. Dietzel (1942) introduced the concept of cationic field strength defined as formal cation charge divided by the cation–anion distance [61]. This concept enables a quantifiable distinction to be made between the three categories of atoms:

1) network formers with a field strength of 1.4–2 N/m,
2) network modifiers with a field strength of 0.1–0.4 N/m, and
3) amphoteric atoms with a field strength of 0.5–1.0 N/m.

Glass formation is favored if the difference in field strength between the cations is larger than 0.3. Smekal (1949) expanded on the cationic field strength concept by taking the bond polarity into account [62]. Glass formation is favored if mixed bonding with a homopolar and heteropolar component occurs. Weyl (1958–1959) postulated the screening theory used to explain the mechanical properties of glasses [63]. In this theory the polymerization of polyhedra to threedimensional random networks is caused by the polarization and deformation of residual valence forces. Stevels (1948) developed a theory for invert glasses, which contain polyhedra with less than three connected corners in contradiction to the Zachariassen postulates [64]. His structural parameter Y is a measure of the average number of bridging anions. The properties of the glass are mainly determined by the network modifier atoms when Y is smaller than 2. This is due to the fact that these network modifiers compete for the available anions, thus resulting in an increased degree of disorder.

Among the less fruitful extensions of the random network theory are those by Huggins and Tilton. Huggins (1955) attempted to explain known discontinuities in properties by assuming the presence of fixed atom groups, called structons [65]. A last refinement of the network hypothesis represents the work by Tilton (1957), who postulated the presence of vitrons: aggregates of silica tetrahedra primarily consisting of five-membered rings, which combined to form a pentagondodecahedron consisting of 20 tetrahedra [66]. These vitrons would be connected to one another by less ordered domains.

With the advent of NMR, laser Raman spectroscopy, and extended X-ray absorption fine structure (EXAFS), focus has been directed to dissecting glass structure in terms of local environments, avoiding any deterministic statements regarding extended structures. An area of research involves determining the extent to which long-range structural elements can be derived from such local environments.

2.1. Structure of Special Melts and Glasses

Almost all industrially manufactured glasses are silicate glasses. As a consequence, these systems are emphasized in the following discussion, the goal being to provide a terminus a quo rather than a terminus ad quem for the study of amorphous materials. The viscosity of various silica-containing melts is used as a reference against which structural concepts can be matched. The use of viscosity is somewhat ironic, however; although viscosity illustrates nicely the role of network-forming atoms in comparison with network-modifying atoms, it is the least understood property of melts or glasses. The structural description of glasses and melts is based on Q (quartz) distribution theory and Q designation. The use of this model enables description of silica species in both solids and aqueous solutions in terms of the distribution of local silicon environments, which are amenable to investigation by NMR. These designations are as follows (Fig. 1):

1) Each silicon atom is coordinated tetrahedrally to four oxygen atoms.
2) If all oxygen atoms in a tetrahedron are connected to two silicon atoms, the local environment around the silicon atom is designated Q_4. All four Si−O bonds of the tetrahedron are, therefore, bridging bonds, designated Si−O(br).
3) The local silicon environments are designated Q_3, Q_2, Q_1, and Q_0 if three, two, one, or zero oxygen atoms are connected to two silicon atoms. In Q_3, three Si−O(br) bonds and one Si−O nonbridging bond, designated Si−O(nbr) exist. For Q_0, all Si−O bonds are Si−O(nbr).
4) Designations Q_4 to Q_0 of local environments coincide with connectivity 4 to connectivity 0 of the extended environment.

Four reactions suffice to describe all possible rearrangements in local environments in those alkali oxide (R_2O) silicate glasses in which all oxygen atoms are connected to silicon atoms [69]:

1) $2\,Q_4 + R_2O \rightleftharpoons 2\,Q_3$ (depolymerization)
2) $2\,Q_3 \rightleftharpoons Q_2 + Q_4$
3) $Q_2 + Q_3 \rightleftharpoons Q_1 + Q_4$ (stepwise condensation)
4) $Q_1 + Q_3 \rightleftharpoons Q_0 + Q_4$

The Q distribution can in principle be determined experimentally by high-resolution solid-state NMR. This distribution does not, however, necessarily relate glass structure to glass properties. Examination of Figure 2 makes this clear. Two hypothetical two-dimensional networks, each containing 45 open tetrahedra and 11 black tetrahedra, are shown. The open tetrahedra represent silicon; the black tetrahedra, lithium in fourfold oxygen coordination. The difference in Q distribution between the two networks is small. Nevertheless, measurement of the transport properties of the two networks would give wildly different results; the arrangement in Figure 2B has very high electrical conductivity and diffusivity (and possibly low viscosity) because of a continuous pathway through the solid in contrast to that in Figure 2A. Clearly the Q distribution does not correlate glass structure with glass properties and additional information is required to make such a connection. This additional information is obtained from Monte Carlo type computer calculations.

Keefer [70] recognized that the question of the structure of a silica-rich alkali-metal silicate glass is analogous to that of electron spin correlation in a two-dimensional Ising model. This model attempts to explain magnetic properties of materials by constructing a lattice with two possible electron spin states, up or down, which allows the problem to be considered in terms of a statistical distribution. Alkali silicate and spin glasses share two characteristics: (1) slow relaxation and (2) a tendency to settle into any one of a large number of atomic configurations. In silica-rich alkali-metal silicate glasses, the two possible spin states correspond to bridging and nonbridging oxygen atoms; silica-rich glass is required because photoelectron spectroscopy has

demonstrated that only in such systems are nonbonding oxygen atoms not present. In the absence of nonbonding oxygen, the ratio between bridging and nonbridging oxygen atoms is fixed by the stoichiometry of the sample.

Figure 1. Structure and designation of silica species; possible number of local environments around a silicon atom up to the third-nearest neighbor [67], [68]

As stated before, connecting Q distribution with physical properties of a glass or melt requires Monte Carlo type calculations. The computational problem involves assignment of the enthalpies of formation of the four principal reactions between Q species; calculation of network patterns; derivation of the thermodynamic properties of the system from these patterns; and use of percolation theory to compute the rheological and transport properties of melts [72]. A rule of thumb is given by Ziman with respect to site percolation [73]: site percolation occurs in a regular three-dimensional assembly when favorable regions occupy ca. 15 % (in the two-dimensional case 45 %) of the total volume.

Figure 2. Two-dimensional nets of silica tetrahedra (△) interspersed with lithium tetrahedra (▲)
A) 36 Q_3, 9 Q_2; B) 33 Q_3, 13 Q_2 Courtesy of J. Dickinson, Corning Incorporated

Local silicon environments can be measured by ^{29}Si magic angle spinning (MAS) NMR. Two problems arise in using this technique: variations in chemical shift for a specific silicon species and, partly as a result of this, limited spectral

resolution. The first problem is illustrated in Figure 3, which shows the ^{29}Si MAS NMR spectrum of $Na_{24}Y_8[Si_{24}O_{72}]$, which is a single-chain silicate with 24 silica tetrahedra per unit cell (a 24er chain in the Liebau classification) and local environment Q_2. The ^{29}Si MAS NMR spectrum of this compound shows 12 peaks with a chemical shift range of 5.12 ppm. Thus, small perturbations in the local environment around one Q_2 species can cause a substantial chemical shift. In this case, the variations are due to chain twisting [71]. Such variations in chemical shift of a single silica species, combined with the large number of species possibly present (ten Q_2 species are possible) and the limited NMR spectral resolution in glass, render determination of the silica species distribution in glass tentative at best. Despite this, some assessment of the degree of intermediate-range order in lithium silicate glasses has been obtained by combining NMR and ESCA (electron spin chemical analysis) results together with the application of proper stoichiometric constraints on the system [69]. Doing this shows clearly that the ^{29}Si NMR spectra of such glasses indicate the presence of only a small number of local environments, in contrast to the total possible number enumerated in Figure 1.

Figure 3. The ^{29}Si MAS NMR spectrum of $Na_{24}Y_8[Si_{24}O_{72}]$
δ (ppm) $= -26.793 - 0.4255\,\theta$ where δ is the chemical shift and θ the $\langle Si-O-Si \rangle$ angle.

2.2. Composition of Glass

Multicomponent glass-forming systems contain, according to Zachariasen, appreciable amounts of elements that form vitreous oxides or other elements that can replace the former isomorphously. Ternary glasses can consist of one network former and two modifiers, two network formers and one modifier, or three network formers. Most ternary oxide systems have been sampled, and investigation has been extended to quaternary and quinary systems.

The properties of complex industrial glasses tend to be rationalized in terms of simple systems. The following discussion, therefore, begins with vitreous silica as the canonical single-component glass, followed by simple two-component systems: the alkali-metal and alkaline-earth silicate, borate, phosphate, and germanate glasses. Boro-, alumino-, and lead silicate glass is then discussed, followed by two nonoxide systems, the chalcogenide and halide glasses. Finally, the chemical composition of industrially important glasses is tabulated.

2.2.1. Single-Component Glass

The most important single-component glass is vitreous silica. The structure consists of corner-sharing SiO_4 tetrahedra. Each oxygen atom is shared by two silicon atoms, forming Q_4 local silicon environments. Long-range order is, of course, absent. Vitreous silica is an excellent dielectric with a very low equilibrium solubility (on the order of 100 ppm at room temperature) in all acids except hydrofluoric. A synopsis of the properties of Corning 7940 fused silica and other amorphous silicas is given in Table 1.

The difference in structure between vitreous silica and two crystalline silicas is shown in Figure 4. Here the frequency of occurrence of average Si−O−Si angles is illustrated by using the ^{29}Si MAS NMR spectrum of vitreous silica [76] and the formula of Thomas and coworkers [77], which relates chemical shift to the Si−O−Si angle. Average Si−O−Si angles vary between 122° and 170° in vitreous silica, the most common value being 147° (or 151° if the spectrum of Gladden and coworkers is used [78]). On the other hand, quartz and cristobalite each have

Table 1. Properties of Corning 7940 fused silica and low-water (<100 ppm) vitreous silica [74], [75]

Softening point, K	1853
Annealing point, K	1357
Strain point, K	1229
Thermal expansion coefficient (273 – 573 K), K^{-1}	5.5×10^{-7}

∗ Data for vitreous silica.

one single Si−O−Si angle, with values of 143° and 146°, respectively.

Superimposed on the plot of Si−O−Si angle versus frequency in Figure 4 is the two-center energy, taken to reflect the bond energy, for a silicon – oxygen bridging bond as a function of Si−O−Si angle, calculated by using semiempirical molecular orbital calculations [79]. Inspection of this curve shows that a Si−O bond with a Si−O−Si angle of 180° is stronger (i.e., has a more negative two-center energy, ca. − 1760 kJ) than that at a Si−O−Si angle of 120° (two-center energy, ca. − 1530 kJ). Examination of Figure 4 suggests that although glasses are intrinsically less stable than their crystalline counterparts, a vitreous silica more stable than quartz or cristobalite is conceivable; the challenge is to make a glass with a larger percentage of Si−O−Si angles >150°. Only this angle must be considered because the energy barrier to rotation between connected silica tetrahedra is negligibly small.

Fused silica transmits light of wavelengths into the UV region and is the oxide glass most resistant to damage caused by radiation. It finds use in windows for space vehicles and wind tunnels, ultrasonic delay lines, crucibles for growing ultrapure silicon or germanium crystals, optical fibers, and optical systems in spectrophotometric equipment.

Vitreous silica can be produced by several methods. These processes and the impurities associated with them are listed in Table 2.

Fused quartz made by electrically fusing quartz crystals has very low moisture content and, hence, good IR transmission for wavelengths < 4500 nm. The disadvantage of quartz as a raw material is that even high-grade pure

quartz crystals contain 1 – 2 ppm of aluminum, alkali, manganese, and titanium. The presence of these elements increases the number of Si–O(nbr) bonds, which thereby reduces UV transmission for wavelength < 4500 nm. Flame fusion of quartz or flame hydrolysis of $SiCl_4$, on the other hand, gives glasses of very high purity except for large amounts of water, which decrease IR transmission. For some applications, impurities as low as 1 part in 10^{12} become important. An example is uranium; this problem is best solved by ensuring that the silica source is biogenic rather than associated with granitic rocks or pegmatites.

2.2.2. Silicate Glasses with Two Components

Two-component silicate glasses are of particular interest in studying glass formation. Addition of alkali-metal or alkaline-earth oxides breaks Si–O–Si linkages, the alkali-metal or alkaline-earth nestling at nonbridging oxygen sites in the network, hence, the description network modifiers. This decrease in connectivity of the silica network manifests itself in a very large decrease

in viscosity (see Table 3), melting point, and UV transmission. Modifiers also cause a decrease in resistivity, an increase in thermal expansion, and generally lower chemical durability.

Different alkali-metal atoms have different effects on the properties of silicate glasses. Thus, lithium silicate glasses are nonhygroscopic, whereas sodium, potassium, rubidium, or cesium silicate glasses show increasingly higher hygroscopicity. Another example is the volume contraction of the silicate network in the presence of lithium and its expansion in the presence of potassium. The almost monotonic variation in cation – oxygen distance, as measured by

Figure 5. Freezing point depression for alkali-metal silicate melts ($10\,R_2O \cdot 90\,SiO_2$) as a function of cationic field strength

The observed chemical shifts relative to tetramethylsilane ($SiMe_4$) are −93.3, −95, −101, and −101.5 for crystalline lithium, sodium, potassium, and cesium disilicate respectively

X-ray diffraction, has led to a variety of schemes for the comprehensive compilation of the properties of alkali-metal or alkaline-earth silicate crystals or glasses. Among these are the cation field energy and field strength, which are the formal cation charge divided by the cation – anion distance and the square of the cation – anion distance, respectively.

Many physical properties of alkali-metal or alkaline-earth silicate glasses change almost monotonically as a function of cationic field strength or energy. For example, the critical

liquid immiscibility temperature decreases linearly as a function of cationic field strength from magnesium to barium silicates, and from lithium to cesium silicates. Similarly, the freezing point depression increases more or less monotonically from lithium to cesium silicates (see Fig. 5), whereas the surface tension decreases (see Fig. 6). Viscosity, refractive index, and density (see Fig. 7) show a minimum for sodium silicate melts.

Even the few ^{29}Si MAS NMR chemical shift data on crystalline alkali-metal silicates suggest a relation between chemical shift and cationic field strength, less negative (downfield) chemical shifts being associated with greater cationic field strength (Fig. 8). More sophisticated analysis of a variety of silica-containing systems has been carried out [83], [84]. In alkali-metal or alkaline-earth silicate glasses, most physical properties vary more or less linearly with cationic field strength, with the exception of viscosity, refractive index, and density. Although it is useful as a mnemonic device, no true cause and effect relations are associated with cationic field strength or energy.

23.5	1.0

2.2.3. Borate, Phosphate, and Germanate Glasses

Borate glasses contain planar BO_3 groups as structural units, rather than tetrahedral SiO_4 groups. The oxygen atoms are, as in silica, again connected to two network-forming atoms, in this case boron. Radial distribution analysis describes the B_2O_3 glass structure as consisting of boroxyl rings, i.e., planar rings containing three boron atoms and three oxygen atoms. Molecular dynamics have shown that the radial distribution pattern is consistent with structures having a low concentration of such rings [85].

Although borate glass forms a three-dimensional network, its viscosity is substantially lower than that of silicate glass, as shown in Table 4. Again, addition of alkali lowers the viscosity of the melt, but the effect is by no means as dramatic as for silicate glass [86].

Introduction of alkali or moisture to alkali-metal borate glasses causes some of the three-coordinate boron atoms to become four-coordinate, as shown by the pioneering NMR work of Bray and O'Keefe [87], [88]. The ratio of three- to four-coordinate boron in alkali-metal borate glasses has an upper limit of about 1.2.

Solid lines indicate experimental data. Dashed lines indicate analytical data.
a) Total spectrum; b) Nonbridging oxygen; c) Doubly bonded oxygen (P = O); d) Bridging oxygen

Phosphate glasses contain tetrahedrally coordinated PO_4 building blocks; however, they do not show the same type of connectivity as silicate glasses. Oxygen 1 *s* photoelectron spectroscopy suggests that in phosphate glasses, three types of oxygen atoms occur: those bonded to two phosphorus atoms, the bridging oxygens O(br); those bonded to one phosphorus atom and one alkali-

metal atom, the nonbridging oxygens O(nbr); and those bonded only to phosphorus, the doubly bonded oxygens O(d). A characteristic oxygen 1 *s* photoelectron spectrum of a phosphate glass is shown in Figure 9. In contrast, silicate glasses never contain double-bonded oxygen atoms and only rarely nonbonded oxygen, i.e., oxygen atoms not connected to at least one silicon atom. An example of the latter is glassy Pb_2SiO_4.

Oxygen 1 *s* photoelectron spectroscopy indicates both the concentration of different oxygen atoms in a material and the actual charges on these atoms. The relation between energy shift of the oxygen 1 *s* photoelectron spectral line and charge is shown in Figure 10. According to this method, quartz, cristobalite, and vitreous silica have an oxygen charge of −0.74. Oxygen atoms with higher negative charge are encountered, for example, in lead silicate glasses, which show oxygen charge variations comparable to those found for superconducting materials. Some oxygen 1 *s* derived charges for various compounds are compiled in Table 5 [90]. Assignment of charges is a partitioning problem without a unique solution.

Some special phosphate glasses show a connectivity of four, identical to that found in vitreous silica. Examples are ZnP_2O_6 and $AlPO_4$ glasses.

The structure of alkali phosphate glasses is well known because these glasses, in contrast to alkali silicate glasses, either do not, or only at very small rates, repolymerize on dissolution in aqueous solution. As a result, the length of the phosphate chains remains unchanged. The relative proportions of different chains in solution, analyzed chromatographically, give a true measure of the distribution of extended environments in phosphate glasses. The most common chain length is three to four phosphorus atoms, with a maximum chain length of seven. No analogies between the distribution of structural elements in phosphate and silicate glasses exist. This is due to the limited cross-linking and branching that occur in phosphate glasses in comparison to silicate glasses due to the presence of P=O bonds.

Phosphate glasses tend to have low durability. Despite this, important commercial applications exist. One of these is associated with the sharper absorption bands of iron oxide in the ultraviolet and infrared in phosphate glasses compared with silicate glasses. Iron-containing phosphate glasses are, therefore, nearly transparent to visible light, enabling the manufacture of virtually clear heat-absorbing glasses containing several percent iron oxide.

Figure 10. Oxygen charge derived from oxygen 1 *s* photoelectron spectra [89]

Phosphate-based glasses are more resistant than silicate glasses to hydrofluoric acid. Some optical glasses produced by Schott, Hoya, Owens-Illinois, and Corning France use phosphate as the primary glass former. Fluorophosphate glasses, designated FK-5 and FK-50 by Schott, have very low optical dispersion, with Abbe numbers of 70.4 and 81.5, respectively.

Germanate and Germanosilicate Glasses. The viscosity of molten GeO_2 (*mp* 1389 K) is 633 Pa · s at 1673 K. For comparison vitreous silica with < 10 ppm water has a viscosity of 8.17×10^8 Pa · s at the same temperature. Addition of alkali lowers the viscosity of molten germania substantially, as shown in Table 6. The GeO_2–SiO_2 glass system finds application in optical waveguides. The variation of viscosity of GeO_2–SiO_2 glass (42.2 mol % GeO_2) with temperature is shown below:

$10^{14.5}$ Pa · s (899 K)
10^{13} Pa · s (992 K)
10^{12} Pa · s (1054 K)

The initial increase in density of molten GeO_2 with the addition of alkali is attributed to changes in oxygen coordination around germanium from tetrahedral to octahedral. This coordination change is associated with the so-called germanate anomaly, which gives rise to observed maxima and minima in property – composition curves (e.g., molar volume, viscosity, acoustic velocity, and heat of solution).

Table 6. Viscosity and density of alkali germanate glasses

20.0		3.18

2.2.4. Borosilicate and Aluminosilicate Glasses

Borosilicate Glasses. Network modifiers cause a change from trigonal to tetrahedral coordination in borosilicate glasses just as in borate glasses. Addition of boron to silica melts reduces the melt viscosity, as shown in Table 7; however, the effect is substantially less pronounced than that produced by addition of alkali to silica melts.

Table 7. Melt viscosity in the B_2O_3–SiO_2 system (1573 K)

B_2O_3, mol %	Viscosity, Pa · s
0 (100 % SiO_2)	1.622×10^{11}
42.4	752
62.4	78.6
71.9	25.4
82.5	10.2
90.0	5.8
93.9	4.4
100.0	3.0

Many technically important glasses have been developed on the basis of the *boron anomaly,* i.e., a minimum or maximum in certain physical properties of alkali borates at 15 – 30 mol % modifier. Replacement of alkali by boric acid decreases the thermal expansion of the

glass. The chemical resistance of these glasses is excellent. Phase separation of borosilicate glasses into silica- and borate-rich parts commonly occurs during heat treatment and is useful in certain applications. For example, Vycor glasses are based on liquid immiscibility in the $Na_2O-B_2O_3-SiO_2$ system. Most commercial borosilicate glasses, however, have compositions that are miscible and homogeneous. Borosilicate glasses are used in ovenware, laboratory equipment, piping, and sealed-beam headlights and in glass fibers for reinforcement, textile, or insulation fiber applications.

Aluminosilicate Glasses. The addition of small amounts of alumina (up to 4 mol %) to silica melts tends to increase the density of the resulting glass, presumably because of the formation of triclusters (i.e., oxygen atoms connected to one aluminum and two silicon atoms). The effect of large amounts of alumina on the viscosity of aluminosilicate melts at 2223 K is comparable to that of Li_2O at 1673 K (see Table 8).

Structural rules, based on X-ray diffraction analysis of crystalline network-modifier aluminosilicates, suggest that aluminosilicate glass has a silica-like structure in which all oxygen atoms are bridging when the molar ratio of alkali metal or alkaline earth to alumina is one. The high viscosity of alkali aluminosilicate melts is supposed to reflect this silica-like structure. For example, a melt of composition $Na_2O \cdot Al_2O_3 \cdot 6\,SiO_2$ (albite) has a viscosity of 230 Pa · s at 1973 K, 582 K above the melting point of the crystalline phase. On the other hand, a melt of composition $CaO \cdot Al_2O_3 \cdot 2\,SiO_2$ (anorthite) is fluid (0.96 Pa · s at 1973 K, 143 K above the melting point of the crystalline phase), indicating that silica-like behavior does not necessarily occur in alkaline-earth aluminosilicate melts. In contrast, however, the viscosity of fused silica at 1973 K is 2.48×10^6 Pa · s, so that neither of the two aluminosilicate melts seems to be particularly silica-like in its rheological properties.

Aluminosilicate glasses are used commercially because they can withstand elevated temperature and be chemically strengthened by alkali-metal or alkaline-earth exchange. Applications, therefore, include airplane and space vehicle windows, frangible containers, lamp envelopes, and cooking utensils.

Table 8. Viscosity of molten aluminosilicates (2223 K)

Al_2O_3, mol %	Viscosity, Pa · s

70.0	0.10
100	0.042 *

* 2327 K.

2.2.5. Lead Silicate Glasses

The $PbO-SiO_2$ system has the largest glass-forming region among oxide glasses. Characteristically, PbO also exhibits extended glass-forming regions with other network formers. The behavior of lead as a network modifier or former is thought to arise from its low coordination number with oxygen, which varies between 2 and 4. Note that although crystalline Pb_2SiO_4 has the orthosilicate composition commonly indicative of Q_0 silica species, its actual local silicon environment is Q_2, the silica tetrahedra in this compound forming Si_4O_{12} rings. In this compound, bridging (Si−O−Si), nonbridging (Si−O−Pb), and nonbonding (Pb−O−Pb) oxygen atoms are present. The last type is tetrahedrally coordinated to lead atoms, forming a quadricluster [91], [92].

Lead glasses can be melted easily; they have a long working range, low surface tension, and high refractive index. These properties make them useful for lead crystal, optical glass, and hand-formed art ware. Lead-containing glasses effectively absorb high-energy radiation and are, therefore, used for radiation windows, fluorescent lamp envelopes, and television tubes. Low-melting solder glasses and frit or decorative enamels are usually based on low-melting lead silicate compositions.

2.2.6. Chalcogenide Glasses

Glasses based on sulfur, selenium, or tellurium rather than oxygen are well known. Chalcogenide glasses are defined as noncrystalline solids from melts of the three chalcogens and

their combination with elements of groups 14, 15, and 17. Structurally such glasses are quite different; they resemble organic polymers rather than oxide glasses. These glasses, although often opaque to visible light, transmit further into the infrared than oxide glasses. Many of the chalcogenide glasses are semiconductors; the conductivity increasing with increasing atomic number. Chalcogenide glasses tend to be much more stable than fluoride glasses.

2.2.7. Halide Glasses

Spectacular developments have occurred in fluoride glass. Before about 1974, the only well-known fluoride glass was BeF_2, with tetrahedrally coordinated beryllium, a viscosity on the order of 10^5 Pa · s at its melting point (813 K), and a connectivity analogous to that observed for silica. Heavy-metal fluoride glasses containing zirconium, barium, and lanthanum (ZBL), with a characteristic viscosity at the melting point (813 K) of ca. 0.1 Pa · s, and the more stable ZBLA glasses (57 mol % ZrF_4, 34 mol % BaF_2, 5 mol % LaF_3, and 4 mol % AlF_3) have been discovered and examined [93]. Their use in optical fibers is discussed in [94]. They are commercially available.

Vitreous beryllium fluoride is a prime candidate in the production of optical waveguides because of its unique spectral properties, including transmission from < 160 to 5500 nm; very low refractive index, $n_D = 1.275$; and very low dispersion, $\nu^{-1} = 9.3 \times 10^{-3}$.

Drawbacks are that it is highly hygroscopic and contains beryllium, which is toxic. The former can be reduced by the addition of aluminum, alkali-metal or alkaline-earth fluorides.

Some difficulties must be overcome in the application of heavy-metal fluorides in waveguides: two of the more serious are poor mechanical strength and scattering loss due to transition-metal ion impurities and crystalline inclusions.

2.2.8. Glasses with Complex Composition

Most industrially important glasses contain a large number of components. The composition of these glasses is given in Table 9. The simple systems already mentioned give some guide about what to expect of the properties and structure in such systems. However, attempts are still being made to relate properties to melt or glass structure even for simple systems. The structure – property relationship in complex systems is still largely obscure, and substantial scope remains in glass production for classical heat and beat treatments.

Figure 11. Observed and calculated nucleation and growth regions as a function of temperature for $Li_2O \cdot 2\,SiO_2$ glass

3. Glass Formation, Crystallization, and Liquid Immiscibility

Glasses are thermodynamically unstable, compared with isochemical crystals. The reason for glass formation can be inferred from the work of Tammann [95], among others, who showed that the crystallization process occurs in two steps: first crystal nuclei form, then these nuclei grow. Depending on the temperature and the substance, either step may determine the rate of spontaneous crystallization. Therefore, at least two free energy barriers are involved in the metastability of the supercooled liquid. The first of these is the free energy of crystal nucleus formation, arising primarily because the melting point of small crystals is lower than that of large crystals. The second barrier is due to impeded molecular motion at the crystal – liquid interface in going from a liquid to a crystal-like position. The two noncoinciding regions of nucleation and growth are shown for the Li_2O – $2\,SiO_2$ system in Figure 11. This figure also

illustrates the discrepancy between the nucleation area derived from classical nucleation theory and that observed experimentally [96], [97].

The rate of crystallization of an undercooled liquid is specified by the rate of both crystal nucleation and crystal growth at the expense of the liquid. With glass, crystallization is called *devitrification,* which occurs when the glass is heated above the glass transition temperature T_g but below the liquidus temperature. Glass transition temperatures are given in Table 10.

Table 10. Glass transition temperatures and melting points for some silicate glasses [80]

Glass	T_g, K	T_m, K
SiO_2	1381	1996
$Na_2Si_3O_7$	790	1073
$Na_2Si_2O_5$	725	1147
$K_2Si_4O_9$	775	1043
$K_2Si_3O_7$	820	1198
$K_2Si_2O_5$	763	1318
$CaMgSi_2O_6$	1026	1665
$NaAlSi_3O_8$	1088	1391
	1028	1391
	1036	1391
$KAlSi_3O_8$	1178	1806
$CaAl_2Si_2O_8$	1086	1826
	1153	1826

In undercooled liquids, nucleation at interfaces (i.e., heterogeneous nucleation) dominates other nucleation processes. Homogeneous nucleation (i.e., nucleation in the interior of the liquid in the apparent absence of an interface) is known for only a few glass systems (e.g., $Li_2O \cdot 2\,SiO_2$, $Na_2O \cdot 2\,CaO \cdot 3\,SiO_2$, and $BaO \cdot 2\,SiO_2$ [98]). Locations in which heterogeneous nucleation occurs are at the air – liquid interface, the liquid container wall, particles or gas bubbles, and boundaries between immiscible regions. A well-known example of the predominance of heterogeneous nucleation is the formation of ice, which nucleates heterogeneously at 273 K and homogeneously in undercooled water at ca. 233 K.

Crystallization in undercooled liquids is controlled primarily by the rate of crystal growth. Nucleation studies by Tamman [95] of silicate melts indicated that the rate of crystal growth increases with increasing undercooling, reaches a maximum, and then decreases with further increase in undercooling. Theoretical studies in the early 1930s showed that the growth rate increases with increasing undercooling, but decreases with increasing viscosity, which accounts for the experimentally observed maximum rate of crystal growth at some intermediate temperature.

A measure of glass-forming tendency is indicated by the reciprocal of the growth rate. Thus, peak growth rates of 2×10^{-6}, 1×10^{-5}, and 1.5×10^{-2} cm/s for cristobalite (SiO_2), GeO_2, and anorthite ($CaAl_2Si_2O_8$), respectively, indicate the first glass to be substantially more stable than the last. Some additional examples are given in Table 11.

As a rule, technical glasses have peak growth rates below 10^{-3} cm/s. Some optical glasses have peak growth rates greater than 10^{-2} cm/s, thereby causing considerable production problems.

Growth rates are generally extremely dependent on composition. Alkali – silica systems are illustrated in Figure 12. Even minor components can substantially influence growth rate and, hence, the ability to form a glass. The role of minor components is usually thought to be one of poisoning the surface of the crystallite.

Nucleation and growth are diffusion-controlled. Glasses, therefore, become more stable with increasing number of components. Consideration of the Stokes – Einstein relation, which describes the inverse proportionality between diffusion and viscosity, suggests that lower diffusion and, therefore, higher viscosity at the melting temperature enhance the glass-forming tendency. Increasing the concentration of network formers, therefore, tends to enhance melt viscosity and decrease crystal growth for the same thermodynamic driving force of crystallization.

In addition to crystalline precipitation, phase separation can occur in specific glass systems. Such separation is usually manifested as changes in color, optical transparency, or chemical durability. Glass systems exhibiting phase separation possess, in a specific temperature region, a miscibility gap characterized at the upper and lower ends by an immiscibility temperature. Liquid immiscibility can be made visible by proper heat treatment, especially in glasses that tend to undergo phase separation, e.g., those found in the silica-rich part of the $Li_2O - 2\,SiO_2$ and alkaline earth – silica systems. The growth rate of the secondary glassy phase, separated from the orig-

Table 11. Measured growth rate of minerals and related substances [80]

Crystal	Composition	Liquidus temperature, K	ΔT at peak, K	Rate at peak, cm/s
Cristobalite	SiO_2	1996	50	2×10^{-6}
Anorthite	$CaAl_2Si_2O_8$	1830	300	1.5×10^{-2}
Diopside	$CaMg(SiO_3)_2$	1664	>100	2.2×10^{-2}

Alkali feldspar	$Ab_{70}Or_{30}\cdot$ 1.7 % H_2O	1243	160	3.2×10^{-6}

inal homogeneous glass, is diffusion-controlled in most cases.

Figure 12. Critical cooling rate as a function of composition for alkali – silica melts (R_2O-SiO_2) [99]

For example, opal glasses may be either translucent or opaque, depending on the particle size and quantity of the second phase and on the difference in refractive index between the second phase and the matrix. Fluorine-containing glasses, which separate into phases containing NaF or CaF_2, are commonly made into pressed items such as tableware. On cooling, such glasses become spontaneously opaque, phase-separating into a silicate-rich matrix and fluoride droplets with dimensions of the order of 10^{-6} m. Other products in which phase separation is used are Vycor glass, photochromic glass, and luminescent and magnetic glasses.

4. Chemical, Mechanical, and Physical Properties of Industrially Important Melts and Glasses

Extensive research has been carried out on the relation between composition and physical properties of multicomponent glass systems. Partial molar coefficients for most physical properties (e.g., expansion, viscosity, heat capacity, and refractive index) have been determined since the pioneering work in this area by WINCKELMANN and SCHOTT [100], enabling calculation of properties for a given composition. Some properties of industrially important glasses are collected in Table 12, 13, 14, 15.

The lack of proper probes to analyze glass structure has prevented derivation of quantitative relationships between glass structure and properties. Qualitative rationalizations in terms of one model or another abound, and with such models, predictions can be made as to the influence of various components on the physical and structural nature of the glass.

The most important property of a glass or melt is its viscosity. Therefore this discussion starts with the rheological properties of glass melts and the three major variables which influence these properties: temperature, time, and glass composition. Next, surface tension of melts is discussed, followed by glass density, thermal expansion, mechanical properties such as elasticity and mechanical strength, hardness, thermal properties, electrical properties, gas permeability, chemical stability, surface properties and optical properties. This chapter concludes with a discussion of the nature of color in glasses.

[e] Code 9608 may be produced in a range of expansion values depending upon intended application. [f] Extrapolated values. [g] Normal service: no breakage from excessive thermal shock is assumed. Extreme limits; glass will be very vulnerable to thermal shock. Recommendations in this range are based on mechanical stability considerations only. Tests should be made before adopting final designs. These data approximate only. [h] These data approximate only. Based on plunging cold sample into cold water after oven heating. Resistance of 100 °C means no breakage if heated to 110 °C and plunged into water at 10 °C. Tempered samples have over twice the resistance of annealed glass.

[1] At 10 kHz. [m] Refractive index may be either the sodium yellow line (589.3 nm) or the helium yellow line (587.6 nm). Values at these wavelengths do not vary in the first three places beyond the decimal point.

4.1. Rheological Properties of Glass Melts

Viscosity determines the optimum melting, forming, and annealing procedures for a glass, as well as the limitations on its use at high temperature. The optimal viscosity regions for these processes are illustrated in Figure 13. A characteristic of glass is that rapid but smooth changes in viscosity occur in the entire region from 10 to 10^{13} Pa · s, provided that no devitrification or crystallization occurs. Molten silicates with vis-

cosity up to 10^3 Pa · s are Newtonian liquids, i.e., liquids in which viscosity is independent of shear stress.

Figure 13. Optimum viscosity regions for forming and annealing glasses

Four types of viscosity measurement exist: (1) stationary methods, which include capillary and falling body; (2) rotation methods, including cone-and-plate and rotating cylinders; (3) oscillating methods; and (4) bending beam methods. No single instrument can measure viscosity over the entire range of interest for glasses. Below 10^6 Pa · s a cone-and-plate or rotation viscometer is used. In the range $10^6 - 10^{11}$ Pa · s, a wire pull method is used. The parallel-plate method covers the $10^4 - 10^8$ Pa · s range. The bending beam method is used for viscosities of $10^8 - 10^{14}$ Pa · s. A synopsis of methods for viscosity measurement is given in [101] and [102].

4.1.1. Temperature Dependence of Viscosity

The temperature dependence of viscosity is shown for some oxide glasses in Figure 14. The working, softening, annealing, and strain points are indicated as reference temperatures. Definition of these points are given by the ASTM.

Figure 14. Temperature dependence of viscosity for some industrial glasses
a) Glass no. 8363; b) Glass no. 0010; c) Glass no. 7070; d) Glass no. 0080; e) Glass no. 7740; f) Glass no. 1720; g) Glass no. 7900; h) Glass no. 7940, fused silica; i) Nitrided 96 % SiO_2

The *working point* of a glass melt is the temperature at which its viscosity is exactly 10^3 Pa · s; the glass is then sufficiently fluid for forming by most methods. The *working range* is the range of surface temperature in which glass is formed into ware in a specific process. The *upper end* is the temperature at which glass is ready for working and corresponds generally to a viscosity of $10^2 - 10^3$ Pa · s. The *lower end* refers to the temperature at which glass is sufficiently viscous to hold its formed shape, corresponding to a viscosity $\geq 10^3$ Pa · s.

The *softening point* is defined, according to ASTM C 338 as the temperature at which a uniform fiber of glass with a diameter of 0.55 – 0.75 mm and a length of 23.5 cm increases its length by 1 mm/min when the upper 10 cm is heated at a rate of 5 °C/min. The viscosity at the softening point depends on the density and surface tension of the glass, and is $10^{6.6}$ Pa · s for a glass with a density of 2.5 g/cm^3 and a surface tension of 0.3 N/m.

The *annealing point* is the temperature corresponding to a viscosity of approximately 10^{12} Pa · s. At this point, internal stress is released to an acceptable value of 1.7 MPa (250 psi) in about 15 min.

Finally, the *strain point* corresponds to the temperature at which internal stresses are reduced to an acceptable level of 1.7 MPa in about 4 h. The viscosity at this temperature is approximately $10^{13.5}$ Pa · s. This point represents the temperature of transition from viscoelastic to brittle behavior. The *glass transition temperature* T_g lies in this viscosity range. The temperature region between the annealing and the strain points must be crossed with welldefined slow cooling rates if strain-free large glass bodies are to be produced. Both annealing and strain points may be determined by fiber elongation, ASTM C 336-71 (1981), or by beam bending, ASTM C 598-72 (1978).

In the parlance of glass science, glass with a high softening point is known as *hard glass*; that with a low softening point, as *soft*. If the temperature interval corresponding to 10^2 – 10^6 Pa · s is large, the glass is called *sweet* or *long* in contrast to *short* glasses with steep viscosity – temperature curves. Long glasses, therefore, solidify more slowly than short glasses on cooling. Combinations of these terms are also used; e.g., fused silica, Corning Code 7940, would be identified as a hard, long glass.

Viscosity decreases with increasing temperature; for liquid metals and simple ionic melts, the temperature dependence of the viscosity can be represented by the exponential equation

$$\eta = \eta_0 \exp\left(E_\eta / RT\right)$$

where η is the viscosity and E_η the activation energy for viscous flow. This Arrhenius-type relation rarely holds for polymeric melts because of depolymerization with increasing temperature. Such depolymerization results in a decrease in the activation energy for viscous flow.

For silicate melts, the temperature dependence of viscosity is adequately represented by the empirical Vogel – Fulcher – Tammann equation

$$\log\eta = A + \frac{B}{(T - T_0)}$$

in which A and B are constants, B being a measure of the activation energy for viscous flow; T_0 is added as a third adjustable constant. A Fulcher and two Arrhenius-type equations for three network-forming pure liquid oxides are given below:

For B_2O_3:

$$\log\left(\eta, \mathrm{Pa{\cdot}s}\right) = 0.198 + 145.1/\left(T - 443\right)$$

For GeO_2(1773 – 1973 K):

$$\log\left(\eta, \mathrm{Pa{\cdot}s}\right) = \frac{1.423 \times 10^3}{T} - 0.4704$$

For SiO_2 glass (1508 – 1608 K) and SiO_2 melt (1973 – 2273 K):

$$\log\left(\eta, \mathrm{Pa{\cdot}s}\right) = \frac{2.7115 \times 10^3}{T} - 0.5884$$

The presence of suspended solid matter or gas bubbles in the melt seriously affects measurement of viscosity. The effect is usually to increase the apparent viscosity. In addition, non-Newtonian behavior is commonly observed in crystal – melt slushes or melted gas bubble foams.

4.1.2. Time Dependence of Viscosity

In some highly viscous melts a dependence of viscosity on previous treatment of the melt and on time has been observed, particularly in the subliquidus area. The reason is that highly viscous undercooled liquids do not relax rapidly enough for the structural elements in the liquid to rearrange themselves in a state commensurate with the ambient temperature.

4.1.3. Composition Dependence of Viscosity

As shown previously, the addition of network modifiers to liquid silicon dioxide, boron trioxide, or germanium dioxide strongly affects melt viscosity. Also, among network modifiers, those with the highest cationic field strength are most effective in reducing viscosity.

Although the effect of network modifiers such as alkali-metal and alkaline-earth atoms is fairly well understood, the same cannot be said for amphoteric oxides (e.g., Al_2O_3, ZnO, or MgO). Their varying role is ascribed to changes

in coordination in melts with strong bases, giving rise to terms such as the germanium, aluminum, or boron anomaly.

Figure 15. Variation in connectivity of crystalline calcium silicates and aluminates [103]
a) $CaO-SiO_2$ system; b) $CaO-Al_2O_3$ system

Consider the $CaO-Al_2O_3-SiO_2$ system as an illustration of the difficulty in deriving viscosity for ternary systems. The known crystal structures in the two binary systems $CaO-Al_2O_3$ and $CaO-SiO_2$ show that addition of calcium oxide to silica decreases the connectivity of the silica network in a regular fashion from Q_4 to Q_0; however, addition of calcium oxide to alumina results initially in a coordination change for aluminum from six- to fourfold, followed by the formation of network aluminates with Q_4 connectivity. These trends are illustrated in Figure 15. The two tendencies, depolymerization of silica and polymerization of alumina, must be taken into account if the viscosity of a $CaO \cdot 2\,SiO_2 \cdot Al_2O_3$ melt is to be predicted. Actual measurements indicate that the viscosity of a $CaO \cdot 2\,SiO_2$ melt at 1973 K is 0.78 Pa · s and for $CaO \cdot Al_2O_3$ 0.11 Pa · s, whereas a melt with composition $CaO \cdot 2\,SiO_2 \cdot Al_2O_3$ has a viscosity of 0.96 Pa · s at the same temperature, which suggests that the $CaO \cdot 2\,SiO_2$ system is viscosity-determining in this ternary system.

The viscosity of the $CaO-Al_2O_3-SiO_2$ system is still amenable to some rationalization. The melting behavior in $CaO-SiO_2$– metal oxide systems is more puzzling. As an example, the variation in the three-phase liquidus boundary between crystalline $CaSiO_3$– crystalline silica – liquid, as a function of a third metal oxide, is illustrated in Figure 16. The liquidus boundary suggests that Cr_2O_3 associates with CaO, which extends the silica field with an attendant increase in viscosity, in contrast to BaO, which decreases the silica field most. One might expect concomitant viscosity variations due to this extension or contraction of the silica field in the $CaO-SiO_2$ field. No compatible data are available to assess whether this is indeed the case. Preliminary ^{29}Si MAS NMR work has not shown variations in the melt structure among (BaO, ZrO_2, Al_2O_3, B_2O_3, TiO_2)$-CaO-SiO_2$ glass systems [106].

Figure 16. Variation in liquidus boundary in the $CaO-SiO_2$ system as a function of a third added component [105]

The above examples serve to illustrate that no acceptable mathematical formulation for the relation between viscosity and glass composition exists; the viscosity of a glass is determined by the superposition of several factors. The dependence of viscosity on composition has been

examined in several systematic studies, but the results are applicable only to special groups of glasses. Examples include the effect of various components on the viscosity of sodium silicate glasses [107] and the determination of partial molar viscosity coefficients for multicomponent naturally occurring melt systems [108].

4.2. Surface Tension

Surface tension is defined as the force needed to increase the surface area of a material by 1 cm^2. The numerical value of this measure of the strength of a surface is expressed in N/m. Surface tension is an important variable for the following reasons: it predicts the degree of wetting between different melts, melt – metal, and melt – tank lining surfaces; it predicts movement toward the surface of ions that decrease surface tension and away from the surface of ions that increase surface tension; and it suggests a means of removing gas bubbles in a melt.

The surface tension of silicate melts is not very sensitive to either composition (Fig. 17A) or temperature (Fig. 17B), compared to melt viscosity. Characteristic values for glasses and other materials are given in Table 16. See also Figure 17.

Table 16. Surface tension of various glasses and reference materials

	Surface tension, N/m	Temperature, K
Soda lime	0.33	1573
Silica	0.275	1673
PbO_2–SiO_2 melt	0.230	1675
B_2O_3 melt	0.081	1173
H_2O	0.073	293
Molten alloy	0.60	

Most of the available data on interfacial tension are for systems of interest in ferrous metallurgy. Frequently, these measurements are made in relation to the study of specific problems such as wetting characteristics of welding fluxes and dispersion of metal droplets in slags. The Slag Atlas contains a discussion of such systems [101].

4.3. Density

The density of most technical silicate glasses is 2.2 – 2.5 g/cm^3. For molten B_2O_3, the density varies between 1.67 g/cm^3 at 723 K and 1.49 g/cm^3 at 1673 K; for a GeO_2 melt at 1473 K, the density is 3.46 g/cm^3; for molten SiO_2, the density variation between 2208 and 2438 K is given by the equation

$$\varrho = 2.508 - 2.13 \times 10^{-4} t$$

For molten Al_2O_3, the density variation over the temperature range 2373 – 2623 K is given by

$$\varrho = 5.370 - 11.46 \times 10^{-4} t$$

Note that in both equations the temperature, *t,* is in degrees Celsius. Components with high molecular mass may increase the density to ca. 7 g/cm^3.

The molar volume derived from the density is related to the average molecular mass of the liquid

$$V = \Sigma x_i M_i / \varrho$$

where V is the molar volume, in cubic centimeters per mole; ϱ is the density, in grams per cubic centimeter; x_i is the mole fraction; and M_i is the gram molecular mass of pure component i. In terms of partial molar volumes v_i, the molar volume is given by the sum

$$V = \Sigma x_i v_i$$

The volumetric deviation from ideal mixing is defined by the difference

$$\Delta V = V - V_{\text{ideal}} = V - \Sigma x_i v_i^{\circ}$$

where v_i° = molar volume of the pure component i.

The density of oxide melts is commonly a linear function of temperature over a relatively wide range. Densities are often calculated by using additive relations such as the following:

$$\frac{1}{\varrho} = \frac{1}{100} \Sigma \left[p_i / \varrho_i \right]$$

where ϱ is the density, ϱ_i the calculated partial molar or mass density coefficient, and p_i the concentration of component i in the liquid, in mol %

Figure 17. Variation of melt surface tension

B) With temperature: a) 39.2 CaO · 15.4 Al_2O_3 · 45.7 SiO_2; b) 36.5 CaO · 63.5 SiO_2; c) 40 FeO · 5 MgO · 55 SiO_2; d) 30.3 Li_2O · 69.7 SiO_2; e) 30.1 Na_2O · 69.9 SiO_2; f) 33.4 PbO · 66.6 SiO_2; g) 31.2 K_2O · 68.8 SiO_2; h) 32 Rb_2O · 68 SiO_2; i) B_2O_3

or wt %. Coefficients for calculating the density of soda lime – magnesia glasses in weight percent on the basis of p_i are given below [109]:

SiO_2	2.20
Na_2O	3.47
CaO	5.00
MgO	3.38
Al_2O_3	2.75

Density is somewhat dependent on the degree of cooling, slow rates of cooling giving a higher density. Density measurements are frequently used as quality control indicators in glass plants because this property is very easy to measure (sink – float technique) and deviations from established standards indicate changes in glass composition.

4.4. Thermal Expansion

The thermal expansion of glass is an important property in many applications. Thermally induced stress frequently imposes operating limits because the stress is directly proportional to the rate of expansion. The feasibility of glass – metal seals, processing, annealing, tempering, and strengthening depends on thermal expansion. Thermal expansion is also a factor in determining the ability of a glass article to survive thermal shock and thermal cycling.

Like most materials, glasses expand on heating and contract on cooling. Hysteresis is rarely observed if thermal cycling is sufficiently slow. The linear expansion coefficient α is defined by:

$$\alpha_{\Delta T} = (L/L_0)\,(\Delta L/\Delta T)$$

where L_0 is the initial length, L is the length measured at temperature T, and ΔL the change of length with a temperature change of ΔT. The linear expansion coefficient is used extensively in the glass industry. The variation of linear thermal expansion coefficient with temperature is shown in Figure 18. The average coefficient of linear expansion in the range 273 – 573 K is de-

termined on annealed samples, as specified in ASTM C 598-72 (1978).

Figure 18. Variation in linear expansion as a function of time a) Undercooled fluid; b) Contraction curve on slow cooling; c) Contraction curve on fast cooling; d) Slow reheating of (c)T_g and T_g' are the glass transition temperatures upon slow and fast cooling, respectively.

Figure 19. Linear thermal expansion coefficients for some industrial glasses
a) Glass no. 1990, Iron sealing; b) Glass no. 0120, Dumet sealing; c) Glass no. 7052, Kovar sealing; d) Glass no. 7740; e) Glass no. 7900, 96 % silica

Expansion curves are generally nearly linear up to the glass transition temperature. Above this, thermal expansion increases by a factor of ca. 3 – 4 because of variations in vibrational amplitudes. The point at which the extrapolated slopes of both segments of the curve intersect is defined as the *transformation temperature* of the glass, according to DIN 52 324.

Inspection of Figure 19 shows that the thermal expansion of glasses can differ considerably. Technical glasses are customarily classified according to their coefficients of expansion:

Low expansivity: $\alpha < 60\times10^{-7}\,K^{-1}$
High expansivity: $\alpha > 60\times10^{-7}\,K^{-1}$

Characteristic values are

Pyrex $32\times10^{-7}\,K^{-1}$
Soda lime glass $90\times10^{-7}\,K^{-1}$
Cesium borate glass $30\times10^{-7}\,K^{-1}$

Pure SiO_2 glass has a linear expansion coefficient α of $5.0\times10^{-7}\,K^{-1}$ at 293 – 573 K. Addition of other oxides to silica may increase this value to $125\times10^{-7}\,K^{-1}$. Most technical glasses have a thermal expansion between that of Pyrex ($30\times10^{-7}\,K^{-1}$) and commercial soda lime glasses [$(80-90)\times10^{-7}\,K^{-1}$]. Glasses with expansion coefficients below $60\times10^{-7}\,K^{-1}$ are called hard glasses, whereas those with higher expansion coefficients are designated as soft. This distinction between hard and soft coincides with high and low softening points as discussed previously (Section 4.1.1).

Thermal expansion coefficients may be rationalized in terms of the degree of connectivity of the glass network. Introduction of network modifiers increases the thermal expansion of glasses. In the alkali – silica system, lithium silicate glasses show the smallest thermal expansion and potassium silicate glasses the largest. This difference can be rationalized easily by inspection of thermal expansion and compressibility as a function of coordination number of selected metal –oxygen bonds (Table 17). The observed α/β ratio is approximately constant for many cation octahedra. Changes in bond length during thermal expansion, therefore, tend to be the inverse of those during compression. Lithium, sodium, and potassium, with assumed oxygen coordination variation between four and eight in silicate melts, show a difference in R–O expansion ($\Delta\alpha$) of $42\times10^{-7}\,K^{-1}$. Partial molar expansion coefficients have been calculated and compiled [111].

The transformation temperature has been defined as that point on an expansion – temperature graph at which straight lines drawn to the thermal expansion curves above and below the glass transition temperature intersect. Volume changes in this transformation region are of great practical use. A plot of expansion coefficient versus time is shown in Figure 18. The equilibrium

Table 17. Predicted values of thermal expansion and compressibility for element – oxygen bonds in oxygen-based minerals [110]

volume is reached almost spontaneously above the glass transition temperature. Lowering the temperature and hence increasing the viscosity result in a point being reached at which the volume relaxation time becomes at least as large as the observation time. The cooling glass body does not reach its equilibrium geometry, and a volume change is observed as a result. Thus care must be taken in cooling larger glass bodies to obtain a final product with acceptable low stress.

The feasibility of glass-to-glass or glass-to-metal seals depends, apart from interfacial tension, on the absence of glass reboil and degassing of the metal at the sealing temperature, and on the thermal expansion mismatch of the two materials. For glass-to-glass sealing with acceptable reduced strain, the difference in thermal expansion coefficient generally should not exceed ca. $3 \times 10^{-7}\,K^{-1}$.

The production of glass-to-metal seals is complicated by the substantially larger linear thermal expansion of steel, which varies between $130 \times 10^{-7}\,K^{-1}$ for unalloyed steel and $160 \times 10^{-7}\,K^{-1}$ for stainless steel. Conditions

are relatively simple if thin metal sections are used or if the seal is a so-called compression seal, where the higher expansion metal surrounds the glass and, after cooling, keeps the glass in compression.

Two properties must be controlled to ensure proper glass-to-metal seals. The first involves a complicated and rigorously controlled oxidation – reduction at the interface to form a good bond; the second involves matching the thermal expansion of the glass with that of the metal. The latter causes no problems as long as the glass adjusts to any thermal expansion mismatch by viscous flow. The system must be designed so that below the set point, thermal contractions of the glass and the metal are similar in magnitude and mismatches are taken up preferentially by the metal.

4.5. Elastic Properties

Two classes of variable suffice to describe the mechanical properties of glass: (1) elastic variables and (2) mechanical strength. An *elastic material* has the ability to recover size and shape after deformation. An ideal elastic material deforms instantaneously when subjected to stress, and the deformation recovers instantaneously when the stress is removed. Elasticity is measured as Young's modulus E, which is defined as the ratio between linear stress and collinear strain for a rod or bar, or as bulk modulus K, if a uniform compressive stress is applied to a body. The compressibility K is the inverse of the compressive stress. Measurement of the elastic modulus on annealed samples is described in ASTM C 623-71 (1981) and entails testing the deformation of a material in the direction of the applied force.

$$E = \sigma / \varepsilon$$

Here E is the proportionality constant between applied stress, σ, and the resulting strain, ε. The ratio of the resulting lateral stress to the applied longitudinal stress is the Poisson ratio σ. For shear stress, the proportionality constant is the shear modulus G. The relation of Young's modulus E, bulk modulus K, shear modulus G, and Poisson ratio σ is as follows:

$$E = 3K\,(1 - 2\sigma) = 2G\,(1 + \sigma)$$

Glasses are perfectly elastic: the deformation is directly proportional to the applied stress, independent of loading rate, until failure. A high-modulus glass is one in which the atoms are closer together or the bonds are stronger and hence more resistant to deformation. Vitreous silica has an elastic modulus of about 72.9 GPa, a shear modulus of 31.3 GPa, and a Poisson ratio of 0.165. Below ca. 1273 K it is close to an ideal elastic body under most loading conditions. It deforms instantaneously, does not creep (i.e., deform slowly under continuous load), and recovers instantaneously on removal of the load. Introduction of alkali in vitreous silica decreases the connectivity and hence the elastic modulus. Some elastic constants for alkali silicate and other glasses are collected in Table 18.

The modulus can again be increased by adding network formers (e.g., B_2O_3 or Al_2O_3) to alkali silicate glasses, as illustrated in Table 16 for the sodium – alumina – silica system. Similar results can be obtained by adding oxides (e.g., CaO, MgO, La_2O_3, or ZrO_2). Relatively high moduli are encountered in alkaline-earth aluminosilicate glasses, with values as high as 118 GPa. Elastic moduli normally tend to decrease with increasing temperature and increase with increasing pressure, approaching zero only above the glass transition temperature.

Vitreous silica, Pyrex, and some other glasses with low modifier concentrations, behave anomalously: the elastic modulus increases with increasing temperature. The rationalization for this is the uncommonly small thermal expansion coefficient of the Si–O and B–O bonds, which have thermal expansions of zero between 296 and 1273 K.

4.6. Mechanical Strength

The theoretical strength of a glass is extremely high ($> 10^4$ MPa) when the energy required to break chemical bonds is calculated. In practice, however, measured strengths are much lower and vary widely. Typical values are ca. 10^4 MPa for glass fibers, 10^2 MPa for flame-polished silica rods, and 7×10^3 MPa for thin-walled freshly drawn glass. The reason for the discrepancy between theory and practice, as well as the

Table 18. Elastic constants of silicate glasses [74]

Composition, mol %	E, GPa	G, GPa	K, GPa	σ
$20\,Li_2O \cdot 80\,SiO_2$	76.99	31.40	46.81	0.226
$20\,Na_2O \cdot 80\,SiO_2$	61.08	25.18	35.46	0.213
$20\,K_2O \cdot 80SiO_2$	49.04	19.75	31.62	0.242
$20\,Cs_2O \cdot 80\,SiO_2$	37.67	14.86	27.02	0.274
$20\,Na_2O \cdot 20\,Al_2O_3 \cdot 60\,SiO_2$	73.2	30.6	40.13	0.196
$30\,PbO \cdot 70\,SiO_2$	50.13	21.35	25.63	0.174
$25\,MgO \cdot 25\,CaO \cdot 50\,SiO_2$	99.14	38.81	74.11	0.277
$25\,MgO \cdot 25\,BaO \cdot 50\,SiO_2$	79.52	30.97	61.24	0.284

scatter in data, is the inclusion of many surface and internal flaws that act as stress concentrators or risers. Fracture is usually in the tensile, as opposed to the compressive, mode due to this type of stress concentration. The useful strength of glass articles is, therefore, only a fraction of the theoretical value.

The susceptibility of glass to stress corrosion additionally reduces the practical strength of a glass article by a further 30 % in long-term usage. In building construction, the maximum allowable tensile load on a soda lime glass is 7.0 Pa under sustained loading (at least 1000 h). The chemical composition of glass has a significant effect on its design strength. The allowable stress for glasses with greater resistance to stress corrosion (e.g., fused silica) can be twice as high as that for soda lime glass.

Plastic deformation of glass is prevented by its high viscosity at room temperature, combined with the absence of slip planes. Broken bonds resulting from excessive stress tend not to anneal but function as nucleation sites for cracks, unless enough time passes for rounding of the tips due to aging or zero stress corrosion. If the crack grows, the stress intensity concentration at the tip increases. Those bonds that were intact will break, causing glass fracture.

Glass can be made more load-resistant in several ways: The number of surface flaws can be reduced, by careful handling, annealing after forming, or acid etching. The highest-strength common glass articles are optical waveguide fibers that remain untouched until a coating which protects the fibers from mechanical abuse is applied. Secondary treatment, such as ion exchange, thermal tempering, glazing, differential crystallization, or layering, can induce compressive stresses on the surface of the glass which must be overcome before surface stress reaches the necessary tensile stress that leads to fracture.

4.7. Hardness

Glass hardness is tested in one of three ways: scratching, grinding or abrasion, and penetration. Results obtained with these methods, can be correlated to some extent. However, the hardness sequence for a series of glasses may depend on the method. The most commonly used is Knoop hardness, measured with a diamond pyramid indenter. Historically, Moh's scale of scratch hardness has been employed. On this scale, glass hardness lies between that of the calcium phosphate apatite, with a hardness of 5, and quartz, with a hardness of 7. Common materials that are hard enough to scratch glass include diamond, agate (amorphous SiO_2), sand, silicon carbide, hard steel, and emery. Glass itself can be used as an abrasive.

4.8. Thermal Properties

Heat transfer and transport in melts and glasses are important variables in the design and control of material processing at elevated temperature. They occur in two ways in rigid glass: conduction and radiation. In a glass melt convection also transports heat. In dielectric (i.e., polarizable) materials, two independent modes of heat transfer operate: thermal (phonon) conduction due to lattice wave propagation, and radiative (photon) conduction due to absorption and reradiation of electromagnetic energy. At low to moderate temperature, the transfer of thermal energy occurs primarily by phonons; at elevated temperature, heat transfer by photons predominates. Knowledge of heat transfer is essential

in growing crystals from semitransparent melts and in melting, annealing, and forming glasses. Heat-transfer values are also an important prerequisite for the construction of furnaces, molds, and energy balances in glass technology.

Thermal conductivity is measured in watts per meter per degree; the room temperature thermal conductivity of glass is 0.67 – 1.38 $W\,m^{-1}\,K^{-1}$. Common glass compositions have thermal conductivity values near the upper end of the range. Conductivity increases by ca. 25 % from room temperature to 473 K. Radiative heat transfer appears in clear glasses around 800 K and becomes the major source of heat transport at higher temperature. Vitreous silica has the highest thermal conductivity at room temperature (1.38 $W\,m^{-1}\,K^{-1}$), and high lead silicate glass has the lowest (0.71 $W\,m^{-1}\,K^{-1}$). For Corning Code 7740, a Pyrex brand glass, the thermal constants are as follows: thermal conductivity (298 K), 0.96 $W\,m^{-1}\,K^{-1}$; mean specific heat (298 – 448 K), 0.84 $J\,g^{-1}\,K^{-1}$; thermal diffusivity, 0.56 $mm^2\,s^{-1}$; and emissivity coefficient, 0.94.

The common heat capacity of glass at room temperature is ca. 0.837 $J\,g^{-1}\,K^{-1}$. Glasses that contain atoms of high atomic mass show somewhat lower specific heats (e.g., 0.5 $J\,g^{-1}\,K^{-1}$ for a 50 wt % PbO – silicate glass). The specific heat increases slightly with increasing temperature, e.g., for vitreous silica: 0.73 $J\,g^{-1}\,K^{-1}$ at 298 K; 1.12 $J\,g^{-1}\,K^{-1}$ at 773 K; and 1.21 $J\,g^{-1}\,K^{-1}$ at 1273 K. An average value of 1.05 $J\,g^{-1}\,K^{-1}$ in the region 273 – 873 K is typical.

4.9. Electrical Properties

Electrical conductivity in industrial glasses is associated with the transport of ions. The temperature dependence of electrical conductivity in glasses is positive; conductivity increases with increasing temperature. This property of glass is useful in electrical engineering, where low conductivity is required at ambient temperature, and in electric melting of glass, in which corrosion-resistant electrodes are submerged in the melt and the relatively low electrical resistance of the melt itself at high temperature is used. Electrical resistance R, is defined by the following equation:

$$R = \varrho l / a$$

where ϱ is the resistivity, a is the cross-sectional area perpendicular to the direction of current flow, and l is the length of the sample. Electrical conductivity is defined as the inverse of resistivity. Log ϱ is reported at 523 and 623 K for comparative purposes and to establish temperature dependence.

Figure 20. Volume resistivities for some industrial glasses a) Glass no. 8058; b)Glass no. 0080; c) Glass no. 7740; d) Glass no. 7900; e) Glass no. 7070; f) Glass no. 7040; g) 33 $CaO \cdot 67\,B_2O_3$; h) Glass no. 9753

The electrical conductivity at room temperature for common silicate glasses is 10^{-10} – $10^{-11}\,\Omega^{-1}\,cm^{-1}$, indicative of their good insulating properties. Glass can be used as an electrical insulating material (→ Insulation, Electric). The value $T_{K=100}$ is the temperature at which a glass has a specific conductivity of $10^{-8}\,\Omega^{-1}\,cm^{-1}$. For window glass, which is not a particularly good electrical insulator, this temperature is between 423 and 473 K. Water layers on the surface of glass at low temperature may increase surface electrical conductivity by a factor of 10^3. Some examples of volume resistivity are shown in Figure 20.

In highly connected liquid oxides such as B_2O_3, GeO_2, and SiO_2, electrical conductivities are typically $<10^{-5}\,\Omega^{-1}\,cm^{-1}$ at the melting point, consistent with the high viscosity. Melts of network-modifying oxides, on the other hand, have low viscosity ($<0.05\,Pa \cdot s$) and high specific conductivity ($>1\,\Omega^{-1}\,cm^{-1}$) at the melting point, indicating dissociation into M^{n+} and O^{2-} ions. Most of these molten oxides have higher conductivities than molten salts, indicating that both electron conduction and ion conduction occur. This is particularly true when the metal atoms have a variable valence (e.g., Fe^{2+} and Fe^{3+} in liquid iron oxide). A characteristic of ionically conducting melts is that their specific conductivity increases sharply on fusion, in contrast to melts that conduct by means of electrons.

Specific conductivity in melts depends on the type and amount of alkali ions present. Some examples are given in Table 19.

Table 19. Electrical conductivity of molten alkali borates and silicates

R_2O, mol %	Conductivity, $\Omega^{-1}\,cm^{-1}$
$10\,Li_2O \cdot 90\,B_2O_3$	0.051 (1273 K)
$10\,Na_2O \cdot 90\,B_2O_3$	0.045 (1273 K)
$10\,K_2O \cdot 90\,B_2O_3$	0.040 (1273 K)
$Li_2O - SiO_2$ [a]	1.7 – 6.3 (1773 K)
$Na_2O - SiO_2$ [b]	0.64 – 1.8 (1773 K)
$K_2O - SiO_2$ [c]	0.40 – 1.1 (1773 K)

[a] Li_2O 33 – 58 mol %.
[b] Na_2O 19 – 34 mol %.
[c] K_2O 18 – 34 mol %.

Mixtures of alkali-metal oxides in silicate, borate, or phosphate glasses give rise to anomalously low electrical conductivities. This effect, which is not well understood, is called the *mixed alkali effect.* An example is the specific conductivity of a $Na_2O \cdot K_2O \cdot 4\,SiO_2$ glass ($10^{-12}\,\Omega^{-1}\,cm^{-1}$) which is much smaller than that of either $Na_2O \cdot 2\,SiO_2$ glass ($10^{-8}\,\Omega^{-1}\,cm^{-1}$) or $K_2O \cdot 2\,SiO_2$ glass ($10^{-9}\,\Omega^{-1}\,cm^{-1}$). This effect is not limited to cations such as alkali metals but also occurs with anions (e.g., halides). In this case, it is called the *mixed halide effect.* This effect has been characterized in lead silicate glasses [112].

The temperature dependence of electrical conductivity is given by the relation:

$$\log(1/\varrho) = A - \frac{B}{T}$$

The activation energy for charge transport is lower above the glass transition temperature. The activation energy E for alkali-metal silicates is 35 – 50 kJ and is virtually independent of composition or type of cation present. For alkali-metal borates, the activation energy is about twice as large. The activation energy for alkaline-earth silicates is about 180 kJ at 20 mol % R_2O and decreases to about 85 kJ at 60 mol %, values similar to those found in borate melts. For iron, manganese, and lead silicates, E is about 40 kJ lower than for alkaline-earth silicates. For all these silicate melts, E is about 40 kJ lower than the activation energy for viscous flow. This activation energy is determined by measuring the temperature dependence of the melt viscosity.

The static *dielectric constant* represents the ratio of the energy of the electric charge stored between two metal plates with the material as insulator to the energy of the electric charge stored between the same plates with vacuum as insulator. The magnitude of the dielectric constant depends on the polarizability of the glass constituents. Pure vitreous silica, with its very low polarizability, has a dielectric constant of 3.7. High lead glasses can have a dielectric constant at ca. 15, and specialty glasses with high PbO, BaO, or TiO_2 content have a dielectric constant of ca. 60. The numerical value of dielectric constant can be estimated for most industrial glasses (except for vitreous silica) by using the empirical formula:

$$\text{Dielectric constant} = 2.2 \times \text{density}$$

where the density is expressed in grams per cubic centimeter.

The *dielectric loss,* a dissipative factor, is a measure of the deviation of a material from an ideal dielectric. Generating an electric field in an insulating material introduces a specific quantity of electrical energy. If this energy is partially recoverable, the material is called a dielectric. The irrecoverable part of the energy is lost as heat. The ratio between irrecoverable and recoverable energy is called the *dielectric loss.* At least three types of dielectric loss can be distinguished: resonance vibrational losses, migration losses caused by mobile ions, and deformation

losses related to defects in the silicon – oxygen network.

Dielectric loss depends strongly on frequency. Conductivity and relaxation losses dominate at low temperature. The influence of composition on energy loss in this temperature region is comparable to that observed for electrical conductivity. Dielectric losses have a minimum value at room temperature in the range of $10^6 - 10^8$ Hz. Losses for common glasses in this frequency range vary between 10^{-2} and 3×10^{-2}. Dielectric loss can be lowered to $<10^{-3}$ (10^6 Hz, 298 K) in specialty glasses, usually PbO – BaO rich or mixed alkali borosilicate glasses. Vitreous silica has still lower loss.

Dielectric failure may be due to discharge or arcing, thermal failure, or intrinsic breakdown. In *thermal failure,* electric losses within the dielectric raise its temperature, which in turn increases the losses and flow of current. Breakdown occurs when this cumulative action results in instability. *Intrinsic breakdown* is associated with defects and voids in the glass. The intrinsic dielectric strength of glass is high, e.g., for silica, borosilicate, soda lime, and lead – alkali, values are 5000, 4800, 4500, and 3100 kV /cm (d.c.), respectively, for thin sections.

4.10. Gas Permeability

The permeability of glass to gas is important in high-intensity tungsten – halogen lamps. The glass must be able to withstand leakage of pressurized halogen at elevated temperature. The volume of gas that permeates through glass is directly proportional to the time of exposure, the area of the glass, and the difference between ambient and gas pressure, and is inversely proportional to the thickness of the glass:

$$V = \frac{ktAp}{l}$$

where t is time, A is area, p is pressure, l is thickness, and k is a constant. The constant of proportionality k is thus given by the equation:

$$k = \frac{Vl}{tAp}$$

Gas permeation is also strongly dependent on temperature, as is shown by plotting k as a function of temperature (see Fig. 21).

Figure 21. Dependence of gas permeation upon temperature for 96 wt % SiO_2 glass (Corning code 7900)
The constant of proportionality, k, is plotted as a function of the temperature.

4.11. Chemical Stability and Surface Properties

The chemical stability of a glass depends on its chemical composition and on the medium with which it is in contact. The solubility of amorphous silica is illustrated in Figure 22 and of alumina, a typical amphoteric element soluble in both acids and bases, in Figure 23. Such amphoteric solubility behavior is commonly determined by the ability of an element to change its coordination state as a function of pH. Thus, in the case of alumina, the prevailing solution species at high pH has aluminum coordinated tetrahedrally to four hydroxyl groups $[Al(OH)_4]^-$. At low pH, the prevailing solution species is an aluminum atom surrounded octahedrally by water molecules, $Al(H_2O)_6^{3+}$. If these coordination changes are considered as a function of pH, the formation of zeolites containing only fourfold oxygen-coordinated aluminum atoms in neutral or alkaline environment is certainly no coincidence, whereas clay minerals with sixfold oxygen-coordinated aluminum atoms are always formed in an acidic environment.

Figure 22. Solubility of amorphous SiO_2 as a function of pH [113]
a) Insolubility domain; b) Stable multimeric domain; c) Mononuclear wall; d) Mononuclear domainSolution NMR shows that silica speciation at high silica concentration is more extended than indicated here [67]. At low silica concentration and neutral pH silica dimers occur [114]. The mononuclear wall (dashed line) and mononuclear domain indicate the region in which mononuclear silicon species occur, as shown by potentiometry.

Figure 23. Solubility of amorphous Al_2O_3
The numbers represent the x and y values for a specific solution species. ^{27}Al solution NMR shows fewer species than indicated in this diagram [103], [104].

The solubility behavior of alkali-metal aluminosilicate glasses can be inferred qualitatively from that of silica and alumina. A review of glass – water interactions and solubility has been published [115].

Vitreous silica is soluble to about 100 ppm in acidic or neutral solution (Fig. 22). The corrosion of alkali silicate glasses in such solutions involves an exchange between alkali-metal atoms and protons in a diffusion-controlled process. The silica framework is thought to remain intact and is presumed to form a silica gel-like protective surface layer. Only in leaching with hydrofluoric acid or concentrated phosphoric acid is the silica framework itself attacked. In a diffusion controlled process such as the alkali-metal atom enchange, the rate of dissolution decreases as the square root of time during glass leaching.

The temperature coefficient of glass leaching reactions increases by a factor of ca. 1.5 for every 10° increase in temperature. Increasing the network-former content or doping with multivalent cations strengthens the network. Next to vitreous silica, borosilicate and aluminosilicate glasses have the best acid resistance. No protective gel coating is formed during acid leaching of phosphate or borate glasses; therefore, these glasses are not very resistant to acidic solution.

Alkaline attack involves dissolution of the glass framework and formation of anions of silicic acid. Glasses strengthened with CaO, MgO, Al_2O_3, or B_2O_3 increase corrosion resistance against bases. The most corrosion-resistant glasses are those with substantial ZrO_2 content.

Glass corrosion can be used to advantage. One industrially important class of materials consisted of the soluble silicates. These are solutions with a viscosity on the order of 1 mPa · s, manufactured by dissolution primarily of sodium or potassium silicate glasses in pressurized steam. A review of their industrial uses is given in [116].

Water dissolution can be considered a combination of acid and base attack. First, the pH of the water increases by inclusion of protons in the glass network at the expense of alkali metal; this is followed by attack of the network in the resultant basic environment. Base attack plays a particularly prominent role in glasses because of daily fluctuations in climate. Morning dew causes proton – alkali metal exchange, followed by an increase in alkali-metal concentration on evaporation, which enhances attack by alkali.

For industrial purposes, weathering is defined as corrosion by atmospheric-borne gases and vapors, such as water or carbon dioxide. The acid resistance of glasses is classified by their behavior in 5 % hydrochloric acid at 368 K (95 °C) for 24 h.

Metal or metal halide attack on silica glass at elevated temperature is especially important in light-bulb production. Reaction between vitreous silica and various metals or halides occurs at elevated temperature. Thus, although alkali metals stain glass only at relatively low temperature (<573 K), severe induced devitrification can occur at higher temperature (ca. 1173 K); with attendant glass failure. A 1-h exposure of silica tubes to sodium vapor below 1273 K causes failure due to devitrification. Other elements that induce devitrification at 1523 – 1623 K are Mn, Sn, Fe, and Zn. Metal halides that react with vitreous silica below 1473 K are LiCl, NaCl, $SnCl_2$, NaBr, and KBr. At 1473 – 1673 K, RbCl, CsCl, NaI, KI, $MgCl_2$, $CaCl_2$, $BaCl_2$, and $AlCl_3$ cause failure.

Surface Properties. The acid-base properties of glass surfaces in aqueous solution depend on the point of zero charge (pzc), i.e., that pH at which the surface is not charged. The surface is positively charged if the pH is lower than the pzc, and negatively charged if the pH is higher. The reason for this change in surface charge is that metal oxide surface chemistry in water is dominated by the following reactions [117].

$$\mathrm{MOH_2^+} \longrightarrow \mathrm{MOH} + \mathrm{H^+} \quad \mathrm{p}K_1$$
$$\mathrm{MOH} \longrightarrow \mathrm{MO^-} + \mathrm{H^+} \quad \mathrm{p}K_2$$

Here M represents a surface metal ion and OH is the surface hydroxyl exposed to the medium. The two reactions indicate that a positive surface charge is associated with Bronstedt acidity (proton donor) whereas a negative surface charge is associated with Bronstedt basiscity. The point of zero charge (pzc) is the average of the two pKs:

$$\mathrm{pzc} = \frac{\mathrm{p}K_1 + \mathrm{p}K_2}{2}$$

Some typical values are shown in Table 20.

Table 20. Values of pK_1, pK_2, and pzc for some oxides

Oxide	pK_1	pK_2	pzc
Silica	−2.77	6.77	2.0
Alumina	7.70	9.30	8.5
Titania	5.40	6.40	5.9
Goethite, FeO(OH)	6.99	8.40	7.7

As might be anticipated, a relation between the point of zero charge and cationic field energy can be constructed [118]. High field energy is associated with a pzc at low pH, and low field energy with a pzc at high pH.

The importance of the pzc's of oxides for glasses lies in the fact that pzc's for crystalline and amorphous materials are similar. The pzc's of glasses can therefore be estimated from the pzc's of their constituent oxides. For example, the pzc of quartz occurs at a pH of 2, and the pzc's of the high-silica glasses Pyrex, Vycor, and silica glass occur at a similar pH.

The minimum rate of dissolution of crystalline silicas occurs at their pzc (i.e., pH 2) [119]; this is of importance in adjusting glass compositions for maximum durability.

4.12. Optical Properties

Light transmission, absorption, reflection, and scattering describe the macroscopic aspects of light – glass interaction. The optical properties of glasses can be characterized simply and unequivocally by the spectral transmittance τ_λ as a function of wavelength λ of the irradiating light. Spectral transmittance is the ratio of the light flux Φ_d leaving the glass to the light flux Φ of monochromatic light radiation:

$$\tau_\lambda = \Phi_\mathrm{d}/\Phi$$

The incident light flux can be partitioned over three light – glass interactions:

$$\Phi = \Phi_\varrho + \Phi_\mathrm{a} + \Phi_\mathrm{d}$$

where Φ_d is the transmitted flux, Φ_a the absorbed flux, and Φ_ϱ the reflected flux.

4.12.1. Transmission, Absorption, and Reflection

Light is in part reflected, absorbed, and transmitted. *Absorption* of light requires the operation of an absorption mechanism in the glass. Visible light absorption usually occurs by excitation of electrons from the valence to the conduction band and often results in a change of color of the glass.

The total *transmission* of a glass is determined by reflection at the glass surfaces and optical absorption in the glass. Neglecting multiple reflections between the glass surfaces, the total transmission in air of a flat sample at a specific wavelength is approximately equal to $(1-R)^2 e^{-\beta t}$ where β is the absorption coefficient, t the thickness of the glass, and R the air–glass reflection coefficient. Transmission is a function of wavelength. The lower wavelength transmission limit in ultrapure silica is ca. 150 nm in the ultraviolet. The upper wavelength transmission limit occurs at 5000 nm in the far infrared due to excitation of vibrational states. The lower transmission limit occurs in practice at only ca. 2700 nm because of the ubiquitous presence of water in vitreous silica.

Transmission can be controlled by the type of glass (e.g., silicate, phosphate, or borate) or by the control of coloring additives, oxidizing or reducing melting atmosphere, melting temperature, and cooling schedules. Diffuse transmission occurs in glasses that contain suspended particles (e.g., opal glasses).

Reflectance depends strongly on the quality of the glass surface, the angle of incidence, the indices of refraction of the glass and the surrounding medium, and the wavelength. Reflectance can be specular, as in polished or precision-molded surfaces, or diffuse for ground or irregularly etched ones. The fraction of light of normal incidence reflected by a single plane surface is given by

$$R = [(n-1)/(n+1)]^2$$

in which n is the refractive index of the glass at the wavelength of interest (if the refractive index of air is assumed to be 1). Reflectance loss at normal incidence for simple soda lime glasses is about 4 % per surface, so that 92 % of the incident light is transmitted by a perfectly clear soda lime glass. Glass with a higher index of refraction transmits less light. Thus, glasses with a refractive index of 1.7 and 1.9 transmit 87 and 81 %, respectively, of the incident light. Low-index coating or special surface treatment of glass may significantly reduce losses due to reflection.

4.12.2. Refractive Index, Dispersion, and Optical State

The most important characterizations of an optical glass are refractive index and Abbe number. The refractive index of a glass is defined as the ratio of the velocity of light in a vacuum to that in the glass; larger refractive indices, therefore, indicate lower velocity of light in the material.

Refractive index depends on wavelength, so that values are reported with the wavelength employed. Wavelengths commonly used are the yellow helium D line at 587.6 nm, the green mercury line at 546.1 nm, and the yellow sodium D line at 589.29 nm. The refractive index is generally measured against air, although the refractive index of air is defined against a vacuum ($n_{air}/n_{vac} = 1.00023$). Refractive indices are usually between 1.46 (amorphous silica) and 1.97 (lead silicate glass). Some exotic glasses reach a refractive index exceeding 2.0. Comparison of refractive index variations of amorphous and crystalline silicas and alkali silicate glasses suggests that intra-orbital charge transfer on the oxygen atom, i.e., variation in bonded and nonbonded electron density on the oxygen atom (Fig. 24), are primarily responsible.

The refractive index is proportional to the square root of the number density of dipole oscillators in a material. Thus, the refractive index of amorphous and crystalline silica increases systematically with increasing density (see Fig. 25). Changes in the electronic structure of silica occur concomitantly with density variations, as can be seen from variations in the ^{29}Si MAS NMR chemical shifts. These chemical shift variations result from changes in s electron density at the silicon nucleus (Fig. 26). Thus, the charge on oxygen and silicon in silica varies as a function of density. On the other hand, oxygen 1 s photoelectron spectroscopy indicates that the overall electronic charge on oxygen is -0.74 for vitreous silica, quartz, and cristobalite. This similar-

Figure 24. Change of molecular orbitals into atomic orbitals of silicon and oxygen in a Si—O—Si bond [79]

Figure 25. Variation in refractive index as a function of density for silica
a) Lechatelierite, a natural amorphous silica; b) Tridymite; c) Cristobalite; d) Keatite; e) Quartz; f) Coesite; g) Stishovite

ity in charge on oxygen and, therefore, silicon in crystalline and amorphous silicas suggests that a more subtle variation in electron density is responsible for chemical shift and polarizability variations in silicas.

One subtle variation in electron density in Si—O bonds is associated with shifts in the bonding and nonbonding electron density on the oxygen atom as a function of Si—O—Si angle. Hartree–Fock calculations on $H_6Si_2O_7$ show that although the overall charge on oxygen does not vary as a function of the Si—O—Si angle, the ratio of nonbonded to bonded electron density decreases with decreasing Si—O—Si angle from 1.44 (180°) to 1.07 (120°). This shift in electron density accounts for the increased polarizability of the oxygen atom and for the observed shift of the ^{29}Si MAS NMR resonances to lower field with smaller Si—O—Si angle.

The density of a glass and its refractive index are not necessarily coupled with one another. Plots of density versus refractive index of 20 mol % alkali silica glasses (Fig. 27) show that no clear cause and effect relation between these two variables exists. The reason for the absence of such a relation in the alkali silica glasses presumably lies in the increase in Si—O—Si angle with higher atomic mass alkali atoms, hence decreasing the number density of oscillators with increasing glass density. Alternatively it can be argued that larger Si—O—Si angles decrease the oxygen polarizability, hence accounting for the observed refractive index behavior. The crystal structures of the heavier alkali silicates have not yet been determined. Hence, such increase

Figure 26. Variation in ^{29}Si chemical shift as a function of Si–O–Si angle [66]
The chemical shift is related to the Si–O–Si angle by the following formula: δ (ppm) = – 19.8215 – 0.608526 ⟨Si–O–Si⟩

Figure 27. Variation in refractive index with density for $20\,R_2O - 80\,SiO_2$ silicate glasses

in Si–O–Si angle with heavier alkalis in crystalline alkali silicates is still a matter of conjecture [120].

Optical glasses are usually described in terms of refractive index at the sodium D line, n_D 589.3 nm, and ν value (Abbe number). The Abbe number is calculated from the relation

$$\nu = (n_D - 1) / (n_F - n_C)$$

in which n_F and n_C are the refractive indices at the hydrogen F (486.1 nm) and C (656.3 nm) lines, respectively. The difference $n_F - n_C$ is the average dispersion, and its reciprocal $1/\nu$ is the relative dispersion. Materials with high dispersion have Abbe values around 30; those with low dispersion, around 80.

The refractive index and the Abbe number are incorporated by Schott Glass into a six-digit numbering system used to identify optical glasses. Common spectacles are designated 523 – 586, i.e., $n_D = 1.523$ and $\nu = 58.6$.

Crown glasses have $n_D < 1.60$ and $\nu \geq 55$. They are usually alkali silicate glasses. Glasses such as alkali lead silicate glasses with $\nu < 50$ are designated flint glass. The Schott nomenclature for optical glass is used in Figure 28. Labeled areas represent commercially available glass.

When n_D and ν are identical for glasses with regular dispersion properties, the rule holds that the remaining dispersions are also identical. For standard glasses, the complete refraction behavior can, therefore, be determined from these two variables.

Refractive index and dispersion depend on the structure and constituents of the glass and on their interaction with light. Like most other glass properties, partial molar refractive index coefficients have been calculated.

Measurement of refractive index, although generally requiring some grinding and polishing of the sample, can be carried out with precision and with reasonable speed; it is, therefore, used in quality control to determine the homogeneity of the glass. Dispersion and Abbe number are used mainly to characterize optical and ophthalmic glasses.

4.12.3. Temperature Dependence of Refractive Index

The density of glass and the UV absorption edge vary with temperature. Both effects influence the refractive index, causing in some glasses a negative, and in others a positive, temperature coefficient. Athermal glasses, which do not change their refractive index in specific temperature ranges, are available.

4.12.4. Stress Optical Coefficients

Glass becomes birefringent when strained. Stress and strain are proportional to each other in

Figure 28. Refractive index vs. dispersion and optical classification of glasses
Shaded area indicates region of glass formation. Plexiglass is a methyl methacrylate resin, lucite is an acrylic resin. BaF = barium flint; BaK = barium crown; BaLF = light barium flint; BaSF = heavy barium flint; BK = borosilicate crown; F = flint; FK = fluorocrown; K = crown; KF = crown flint; LaF = lanthanum flint; LaSF = heavy lanthanum flint; LaK = lanthanum crown; LF = light flint; LLF = very light flint; PK = phosphate crown; PSK = heavy phosphate crown; SF = heavy flint; SK = heavy crown; SSK = very heavy crown; TiF = titanium flint

glass. The stress optical coefficient B, or Brewster's constant, expresses the relationship between optical retardation produced in a beam of plane-polarized light as it passes through a glass and the imbalance between principal stresses that exist along the path of this light beam. Brewster's constant is the ratio between retardation R (in nanometer path difference per centimeter path) and stress F (in kilograms per square millimeter)

$$B = R/F$$

The stress optical coefficients vary greatly with glass composition. The value of B ranges from ca. − 1 for extra-dense flint containing 80 % PbO to ca. 2.5 for soda lime glass, ca. 3.4 for 96 % silica glass, 7 for epoxy resin, and 2000 – 14 000 for gelatin.

4.12.5. Radiation Effects

The changes occurring in silicate glass under the action of ionizing radiation (e.g., high-energy electrons, gamma-rays, X-rays, or combinations of these) tend to be the same in both the nature of the excitation process involved and the degree of defect formation. This is true at saturation as long as the same amount of material absorbs the same amount of radiation energy (the energy approximation). Mass absorption coefficients for X-rays are, however, substantially higher than those for ^{137}Cs and ^{60}C gamma rays with energies of 0.66 and 1.17 MeV, respectively. Defect saturation will, therefore, proceed much faster with X than with gamma rays. Color changes induced by sunlight are commonly referred to as solarization.

The stability of glass in a flux of neutrons depends in particular on the amount of boron, which possesses a high absorption coefficient for neutrons. Boron-free glass can generally with-

stand a flux of 10^{19} neutrons/cm^2. Ion bombardment disrupts the glass structure, producing discoloration and free oxygen. The effective lifetime of electronic tubes can be affected considerably by reaction between free oxygen and the cathode.

Electron browning affects the performance of cathode-ray tubes containing oxides of lead or bismuth. These compounds are easily reduced by the incident electrons, producing a brown tint in the glass.

Relatively low doses of gamma rays tend to discolor dense lead silicate glasses. Among amorphous oxides, ultrapure vitreous silica is most resistant to discoloration. The drawbacks of vitreous silica are its low density and the expense of production. Alternatives are glasses with intermediate density to which oxides with variable cation valence are added: Ce_3O_4 (Ce^{3+}, Ce^{4+}) is commonly used as such an oxide because of its effectiveness in increasing color stability. Lead silicate glass combined with intermediate density, cerium-doped glass is used in composite windows with remarkable resistance to radiation damage. They are used, for instance, in environments with relatively high-intensity radiation fluxes, matching the absorption characteristics of heavy concrete used for shielding walls.

Cobalt-containing glasses have been developed for their radiation sensitivity. More sensitive silver phosphate glasses are used as dosimeters to measure exposure to X– or gamma rays.

4.13. Color of Glasses

White light is composed of a mixture of colors, the different colors representing a spectrum of frequencies and hence of energies. The relation between wavelength, frequency, and energy is given in Table 21. The human eye is sensitive to light of frequency $(3.9-7.5)\times 10^{14}$ Hz, corresponding to a wavelength of 400 – 760 nm and an energy of 1.6 – 3.1 eV or 157.4 – 299.1 kJ/mol.

Absorption of a particular component of white light by a transparent material causes the appearance of color. If the material absorbs in the red part of the spectrum, the color is blue; absorption in the yellow region yields a brown color. Thus, for it to have color, some light absorption must occur in the glass.

Limiting wavelengths (lower wavelength limit) of absorption for some oxide and fluoride glasses are given in Table 22. Clearly, in absence of impurities that absorb light in the visible region, none of these glasses shows coloration because no absorption extends beyond 400 nm.

Table 22. Limiting absorption wavelength for various oxide and fluoride glasses

Glass type	Absorption wavelength λT, nm [a]	Energy, eV
P_2O_5	<150 [b]	>8.3
SiO_2	162	7.7
B_2O_3	200	6.2
HPO_3	273	4.5
GeO_2	363	3.4
$P_2O_5-R_2O$ (R = alkali metal)	220	5.6
SiO_2-R_2O	270	4.6
$B_2O_3-R_2O$	360	3.4
BeF_2 [c]	90	13.8
ZBLA [c]	210	5.9

[a] Position of UV edge at 50 % transmission.
[b] Difficult to measure because of the ubiquitous presence of water.
[c] Data from [93], [122], [123].

Transmission curves for some simple uncolored glasses are shown in Figure 29. The UV absorption is of principal importance. This absorption arises from the energy absorbed by electrons excited from the valence to the conduction band as shown in Figure 30. The occupied states are the valence band and the empty states are the conduction band; the energy difference between the two is the band gap. More sophisticated analyses have been made [121].

Figure 29. Transmission curves for simple uncolored glass a) P_2O_5 glass; b) SiO_2 glass; c) B_2O_3 glass; d) HPO_3 glass; e) GeO_2 glass

The widest band gap among the glasses in Table 22 is shown by BeF_2. For oxide glasses, the absorption shifts to longer wavelength in

the increasing order P_2O_5, SiO_2, HPO_3, and GeO_2. A further shift to longer wavelength occurs when alkali-metal oxides are added to the pure network-forming glasses. The degree of shift can be correlated with cation field strength. Addition of Li_2O to a network-forming glass causes the smallest increase in wavelength; addition of Cs_2O, the largest.

Homogeneous glasses and crystals are colorless if the bandgap is sufficiently large. Thus, Al_2O_3, SiO_2, and alkali-metal or alkaline-earth oxides are colorless when pure. Coloring of glass occurs because of the presence of impurities, often *transition metals*, that absorb light in the visible region. The reasons for this absorption are the transition-metal *d* orbitals. The five *d* orbitals, which are degenerate in a free transition-metal atom, are split into two groups under the influence of the ligand electric field. The split in energy between the two sets of *d* orbitals is designated $10\,D_q$. Metal ions and ligand groups can be arranged in a *spectrochemical series*: the metal ions according to the order of increasing $10\,D_q$ developed with given ligand; the ligand groups according to the order of increasing $10\,D_q$ for any given metal ion.

The metal ions fall in the order $Mn^{2+} < Ni^{2+} < Co^{2+} < Fe^{2+} < V^{2+} < Fe^{3+} < Cr^{3+} < V^{3+} < Co^{3+} < Mn^{4+} < Mo^{3+} < Rh^{3+} < Ru^{3+} < Pd^{4+} < Ir^{3+} < Re^{4+} < Pt^{4+}$, and ligands in the order $I^- < F^- < H_2O < SCN^- < NH_3 < SO_3^{2-} < NO_2^- < CN^-$. Tri- and higher valent metal atoms tend to absorb in the visible region in oxide glasses. Electronic transitions between lower occupied and higher unoccupied states have an energy value of 2 – 3 eV.

Figure 30. Calculated direct gap for the $H_6Si_2O_7$ molecule at a Si–O–Si angle of 180°
The direct gap represents the difference in energy between the highest occupied (HOMO) and lowest unoccupied molecular orbital (LUMO).

The degree of splitting of the metal ion *d* orbitals is affected by the coordination number of the metal, oxidation state of the metal, symmetry of the coordination sphere, type of ligand, and nature of the metal ion. Splitting values ($10\,D_q$) for complexes of the first transition series are 800 – 1333 nm for divalent ions and 400 – 714 nm for trivalent ions. Divalent ions, therefore, absorb light outside the visible region and tend to give only weak coloration arising from absorption tails that extend into the red part of the visible region.

Table 23. Transition-metal colors in glasses

Metal	Color
Titanium	no color in low concentration; reduction of Ti(IV) to Ti(III) in high concentration gives slightly violet color; brown in phosphate glasses
Vanadium	vanadium produces a variety of colors because of its variable valence: green in silica glass; colorless in alkali silicate glass; olive green in phosphate glass; brown in borate glass
Chromium	chromium(III) makes glasses green; oxidation leads to chromium(VI) which is yellow
Manganese	manganese(III) makes glasses violet; manganese(II) gives a faint yellow
Iron	iron(II) gives a green color to glasses molten in neutral or slightly reducing atmosphere; iron(III) gives yellow-brown glasses in combination with sulfide (S^{2-})
Cobalt	cobalt(III) gives intense blue color in silicate and phosphate glasses; pink in lowalkali borate glasses; green in glasses with very high alkali content
Nickel	nickel(III) gives olive green or brown color in silicate glasses; higher alkali oxides give yellow; lower content, a greenish brown; blue occurs in some instances
Copper	copper(II) gives blue in silicate glasses; reduction to copper(I) leads to colorless glasses; green in phosphate and borate glasses
Rare-earth metals	cerium gives yellow; praseodymium, weak green; neodymium, red to violet; erbium, pink

Producing a consistent, predictable color in a glass is not trivial, because the same transition metal may give rise to a variety of colors, depending on type of ligands and oxidation state of the metal. This color variability for some cobalt(III) complexes is shown below:

$[Co(NH_3)_6]^{3+}$	yellow
$[Co(NH_3)_5H_2O]^{3+}$	pink
$[Co(NH_3)_5Cl]^{2+}$	purple
$[Co(NH_3)_4Cl_2]^+$,	
cis	red violet
trans	green
$[Co(NH_3)_4(NO_2)_2]^+$,	
cis	yellow brown
trans	yellow red
Multinuclear Co complexes	black

The most common transition-metal oxides used in the glass industry and the expected colors are listed in Table 23. Concentrations are typically 0.5 – 5 wt %. Varying oxidation conditions

can yield results spectacularly different from those anticipated; for example, high-manganese welding fluxes tend to be black to dark purple; however, slightly reducing conditions make such fluxes yellowish green. The colors in Table 23 should, therefore, be regarded only as guidelines.

Striking glasses are the second largest family of colored glasses. Their color is caused by the controlled nucleation and growth of a crystal-like chalcogenide phase. These glasses form the basis of commercial yellow-to-red sharp-cut filters originally produced by Corning Glass Works. The composition of these filter glasses is given in Table 24.

Striking glasses are produced by casting and fairly rapid cooling, which results in a colorless glass. Rapid cooling causes a single burst of nuclei to form with similar dimensions, and reheating causes these nuclei to grow. Color develops (strikes) after heat treatment of such glass between 823 and 973 K. The absorption edge steepens during striking and moves toward longer wavelengths. By controlled reheating, isochemical glasses with different colors can be produced.

The most probable explanation for color generation in striking glass involves an electronic transition from the occupied valence band to the empty conduction band in semiconducting chalcogenide crystals in a silicate matrix. The striking effect is specifically caused by the variation in size of the gap as a function of crystallite size, hence, the name *quantum confinement* for this effect. Typical striking glass chromophores are CdS 2.42 eV (518 nm), CdSe 1.73 eV (717 nm), CdTe 1.44 eV (860 nm), and ZnS 3.53 eV (340 nm) [125]. Of these, only CdS and CdSe absorb in the visible region.

Striking glasses differ from those colored by transition-metal ions mainly by the nearly quantitative transmission of light from a specific wavelength to longer ones. The absorption and transmission regions are separated by a sharp edge, making pure saturated colors possible. These glasses make excellent cutoff filters for optical instruments, unlike filters based on ionic colors with their characteristically broad absorption bands.

5. Production of Glass

Glass-melting technology has passed through six stages:

1) Glass manufacture in open pits ca. 3000 B.C. until the invention of the blowpipe in ca. 250 B.C.
2) The mobile wood-fired melting pot furnace used until about the 17th century by travelling glass manufacturers.
3) The local pot furnace, fired by wood and coal (1600 – 1850).
4) The gas-heated melting pot and tank furnaces dating from 1860, followed by the electric furnace of 1910.
5) Tank furnaces with special designs for obtaining better glass quality (since 1950).
6) All-oxygen-fired glass-melting furnaces (since ca. 1985).

5.1. Raw Materials

Most glass requires heat to convert the raw materials such as minerals and synthetic inorganic chemical components to a homogeneous melt at fusion temperatures that turns to a rigid glass on cooling. Raw materials are selected according to purity, consistency, grain size, water content, availability, pollution potential, ease of mixing and melting, and cost. The most common ingredients in glass production are listed in Table 25.

Today, the most important raw materials are sand and recycled glass cullet. In Western Europe more than 7.5×10^6 t are recycled annually. The primary contaminants are ceramics, organic food residues, and paper. The metal contaminations are almost completely removed from the waste glass in modern post-consumer glass purification plants.

The primary contaminant in sands is Fe_2O_3, followed by minerals such as titania (rutile), zircon ($ZrSiO_4$), and chromia or iron chromites. Acceptable limits for Fe_2O_3 are 0.005 – 0.1 wt %, very much depending on the glass product. Acid-washed varieties of sand have the lowest iron concentrations. The price of sand reflects the quality: varying between \$ 15/t for common glass to \$ 800 – 1000/t for sand with

[a] Sulfates, chlorides, and fluorides are only partly retained in the melt. Sodium, potassium, lead, antimony, arsenic, and boron oxides generally evaporate in small quantities from the melt; retention of these components in the glass is 90 – 99 %. Carbon dioxide and nitrogen oxides are almost completely released from the batch blanket or glass melt. [b] Refractory components. [c] Composition is source-dependent.

an iron content of only 15 – 20 mg/kg. For vitreous silica production, expensive high-quality sands are used.

The main sources of calcium are limestone and dolomite, which also supplies magnesium. About 5 % of the total amount of limestone quarried in the United States is consumed in glass manufacture. Limestone contains 56 wt % CaO, and dolomite 30.0 wt % CaO and 21.5 wt % MgO. High-quality limestone contains < 0.1 wt % Fe_2O_3 and ca. 1 wt % silica and alumina. A source of calcium carbonate for low-iron glasses (ca. 0.02 wt % iron) is aragonite, which is found in high purity in the Bahamas. A drawback of this carbonate is the high content of sulfates and organic material. Other raw materials that are sources of calcium include colemanite and fluorspar, often used in fiberglass production, and iron blast furnace slags, used for soda-lime glasses.

Trona, mined in Trona, Wyoming, is the primary source of soda in the United States. About 40 % of all soda ash produced in the United States is consumed by the glass industry. Synthetic soda produced from common salt (NaCl) is used in Europe and contains small amounts of residual sodium chloride (0.12 – 0.25 wt %). Caustic soda solutions are sometimes used in the wet batching process as a batch component and as a dusting suppressant for subsequent handling. When preparing agglomerated batch in the form of pellets, caustic soda is used both as a binder and as a sodium raw material. Worldwide about 50 % of the soda production is consumed by the glass industry.

Other raw materials for borosilicate glasses include borax and boric acid. Colemanite and ulexite are often preferred as sources of boron on economic grounds. For glass compositions with very low alkali concentrations such as E-glass, colemanite or boric acid is used to avoid an increased sodium content in the glass when using other boron raw materials.

Feldspar and nepheline syenite are common sources of alumina. In the container- and float-glass industries, purified iron blast furnace slags are used as an alumina-rich melting flux. These slags also contain sulfides which decrease the temperatures of primary fining (removal of bubbles, degassing). Litharge is used in the production of lead silicate and lead-crystal glasses. Powdered anthracite, corn starch, oil, raw potatoes, or sugar can be used as reducing agent. Typical oxidizing agents are nitrates such as potassium or sodium nitrate, cerium(IV)oxide, and sodium sulfates.

Most commercial glass compositions contain small amounts of other constituents which, in general, do not significantly affect the physical properties of the glass. *Fining agents* are added in small amounts to eliminate gas bubbles formed during melting. Common fining agents are sulfates, halides (e.g., NaCl), CeO_2, MnO_2, As_2O_5, and Sb_2O_5. These agents are thought to release oxygen, sulfur dioxide, or other gases, increasing the size of the gas bubbles and therefore their buoyancy in the melt. The melts dissolve gases such as carbon dioxide, nitrogen, water vapor, oxygen, and argon that originate from decomposition of the raw material or from the furnace atmosphere. Most of these gases can be removed from the melt by the growing and ascending bubbles during the fining process. Some fining agents, like sodium sulfate, cerium(IV) oxides, antimonates or arsenates also oxidize the glass melt and reduce the iron(II) concentration by oxidation reactions. Nitrates are often used to oxidize batch components such as As_2O_3 (to As_2O_5) and Sb_2O_3 (to Sb_2O_5) in order to make these components effective for primary fining.

Refractory batch components are materials with a high melting point which exceeds the maximum temperatures in the melting tank. These components do not simply melt but dissolve in the primary melts of the other raw materials. Alumina and sand grains, for example, react with and dissolve in sodium-, potassium-, and boron-rich melt phases. The dissolution rates depend on temperature, composition of the primary melts, and the size of the refractory batch grains.

Besides purity, the grain-size distribution of the refractory batch materials is an important factor in successful melting. Too coarse a fraction results in incomplete dissolution of the sand or alumina raw material in the primary melts, with attendant stones and knots in the glass; too fine a fraction results in dusting during handling and too rapid melting, which leads to very fine gaseous inclusions (seeds). The latter may also result in the formation of an insulating alumina or silica-rich scum on top of the glass melt. This scum, due to flotation of very fine silica or alumina grains and subsequent sintering on top of

the melt, can decrease the heat transfer into the melt and slow the rate of melting. In some critical cases, the scum may form silica- or alumina-rich glass defects or cords.

∗ Tyler Standard Screens; note that five other standards are commonly employed: (1) British Standard Test Sieves, (2) Institute of Mining and Metallurgy, (3) the German DIN, (4) the French AFNOR, and (5) the U.S. Standard Sieve Series.

Nework modifiers increase the melting rate and generally decrease the viscosity of the melt. Their effect is to start the dissolution of refractory materials, and to decrease the viscosity and surface tension of the melt. They commonly have a low melting point and high vapor pressure. A low surface tension of the melt improves the wetting of the surface of the refractory batch grains by the aggressive primary melts. Some efficient melting fluxes apart from network modifiers are sodium sulfate, sodium chloride, and calcium fluoride (fluorspar), which have a low surface tension, cullet which needs no fusion energy, and slags containing sulfides and alumina in an easy-to-melt form.

Melting considerations tend to favor grain sizes of refractory batch components that are one to two screen sizes finer than those of commercially available fluxes. Container glass manufacturers generally use sand between 100 and 600 µm (140 – 30 mesh) as the best compromise between melting efficiency and the high cost of producing fine-grained sand. Fiberglass manufacturers, on the other hand, use sand with dimensions < 74 µm (200 mesh). The conversion between mesh size, micrometers, and inches is given in Table 26.

Batches with raw materials having different grain size distributions are sensitive to batch segregation. Most glass melting batches show this behavior during dry transport especially during vibration and free fall. Therefore, water or sometimes light oil is added to prevent demixing during transport and charging of the batch feed into the furnace. Wetting of the batch also reduces the entrainment of fine batch components in the combustion gases in the furnace. This entrainment or batch carryover can lead to batch losses but also to fouling of the flue-gas channels and equipment downstream of the flue-gas ducts.

5.1.1. Chemical Impurities and Decoloration

Pure minerals do not occur in nature. Contaminants such as transition metals, sulfates, halides, or organic matter are always present. Natural or upgraded ores are used, depending on the glass specifications. The most common impurity is iron, whose presence is usually undesirable for clear and flint glasses. Upper limits for this element in some glass products are listed below in percent by weight:

Optical waveguides	10^{-6}
UV transparent Schott glass 8337	0.004
Lead glass	0.018
Ophthalmic glass	0.020
Container flint glass	0.035
Container green glass	0.25 – 0.35
Container amber glass	0.30
Flat glass (clear)	0.07 – 0.1
Tinted flat glass	≤ 1.6
Tableware (clear)	0.02

Other undesirable impurities include primarily the colored oxides of transition metals (e.g., nickel, vanadium, copper, manganese, chromium, cerium, and cobalt). In addition to coloring agents, excess sulfate may cause sulfate gall formation on top of the melt and sodium sulfate inclusion in the glass. Too much sulfate may also lead to precipitation of SO_2 seeds in the glass. Sulfate-containing melts prepared under relatively strong reducing conditions may form SO_2 bubbles which, if not completely removed,

generate low-pressure blisters with sulfur and sulfate deposits in the final product [135]. The presence of chloride impurities in raw materials leads to chloride-containing melts, which may attack the forming molds. Ammonia, coke, sulfides, and organic materials affect the oxygen fugacity (equilibrium pressure of dissolved oxygen gas) of the melt, with attendant reduction of transition metals and subsequent color changes, e.g., reduction of Ti^{4+} (colorless) to Ti^{3+} (blue) or increased concentration of Fe^{2+} due to reduction of Fe^{3+}, or formation of S^{2-}, which forms an amber chromophor in combination with Fe^{3+}.

Impurities are not always undesirable. Small amounts of iron are sometimes necessary to develop a certain glass color. During melting, these impurities often influence heat radiation into the glass, and during forming, they affect the heat loss to the mold or environment. Iron(II) sulfide (FeS) and iron pyrites (FeS_2) produce amber-colored glass used in the container industry. The residual Fe^{3+} forms an iron(III) sulfide oxide complex with S^{2-} giving the glass the amber color. Green container glasses use sodium dichromate or iron chromates. Green and amber container glasses protect beverages, pharmaceuticals, and foods against UV radiation. Selenium, with iron and cobalt, yields a bronze color. In small quantites, selenium, added as elemental selenium, selenite, or selenate, often in combination with cobalt oxides, decolorizes glasses containing iron(II). Selenium plus cobalt oxide give the glass the complementary color of the iron(III) coloring. Cerium dioxide is used to increase UV absorption in optical or colorless soda-lime glass and protects against X-ray browning.

Mass-produced glasses tend to use cheap raw materials with fairly high concentrations of iron. Especially iron(II) gives the glass a green color. Physical or chemical decoloration of such glasses is therefore important. In chemical decoloration, the iron is oxidized to its weakly colored trivalent state by increasing the oxygen fugacity of the melt, usually by adding oxygen-producing compounds such as As_2O_5 (or arsenates), Sb_2O_5 (or antimonates), KNO_3, $NaNO_3$, Na_2SO_4, and CeO_2. Chemical decoloration is effective if the iron concentration does not exceed 0.02 – 0.1 wt %. Physical decoloration is used when the melt contains a higher concentration. Here, the addition of other coloring agents compensates for the yellow-green color of the glass. Common compensating agents are selenium and manganese dioxides with a purple to pink coloration, and the oxides of cobalt, nickel, or neodymium. A side effect of physical decoloration is a reduction in total light transmission.

The redox state, determined by the oxygen fugacity of the melt, determines the color of the glass, because dissolved oxygen has a strong influence on the redox state of polyvalent ions such as iron, chromium, and sulfur in the melt. The color of the glass very much depends on the oxidation state of these ions.

5.1.2. Waste Glass (Cullet)

Waste glass, known as cullet, is an almost universal addition to the batch melted in glass furnaces [136]. In Western Europe some countries, including Germany, the Netherlands, and Switzerland, recycle more than 80 % of the container glass brought onto the market. Recycled cullet saves the resources of other raw materials, requires up to 25 – 30 % less energy to melt than an isochemical batch of raw materials, and, provided it is not too fine, reduces dust during batching and carryover of dust from the batch blanket in the furnace. Optimized furnaces using large cullet ratios in the batches have lower specific nitrogen oxide and carbon dioxide emissions.

Typical amounts of cullet used in different glasses are listed below, in weight per cent:

Container glass	25 – 95
Flat glass	20 – 35
Light-bulb glass	40 – 70
Tableware	25 – 50
TV glass	20 – 45
Insulation glass wool	40 – 45
Commercial glass	50 – 70

In container and insulation-wool glass furnaces, large quantities of external cullet can be recycled. Flat glass, TV glass, tableware, and lighting-glass furnaces use their own cullet or cullet from well-identified sources.

Generally, about 10 – 30 % of the cullet comes from crushed recycled glass produced in the plant. Iron contamination introduced by the crushing process is removed magnetically. Cullet of unknown origin, often collected from bins

specially installed for household glass waste disposal, commonly contains impurities that may be incompatible with the desired quality of the manufactured article, giving unwanted color, stones, crystals, metallic inclusions, cords, or gas bubbles. Metallic impurities in the cullet form liquid metal melts that can react with the refractory and may also cause holes in the bottom of the melting unit (downward drilling). Recycled bottles constitute up to 80 % of the batch used in the container glass industry in some Western European and Asian/Pacific Rim countries. This amount is expected to increase substantially in other parts of the world with the increasing introduction of recycling laws in the United States, Eastern Europe, Canada, and probably South America.

The insulation glass wool industry uses flat glass cullet as one of the main raw materials.

Another waste material added as a raw material to glass melting batches is filter dust separated from the glass furnace flue gases by electrostatic precipitators or baghouse filters. This filter dust often contains sulfates, sodium, and lime, and it can replace part of the sodium sulfate used as a fining agent in the batch.

5.1.3. Preparation of Raw Materials

Accuracy and precision in weighing the various batch constituents are important, because of the required consistency in glass composition. Thorough mixing of ingredients and prevention of subsequent segregation is essential to obtain a homogeneous glass melt. Batch handling systems vary widely throughout the industry, from manual for small production sites to fully automatic (→ Solids Handling). Some glass factories purchase their batches in granulated form (granule size 8 – 20 mm). In large-volume production, each batch material is stored in its own bin, and the correct computer-controlled amount is weighed from the bin onto a conveyor belt that feeds directly into an intensive mixer.

The efficiency of the melting operation and the uniformity and quality of the glass are often determined by the conveyance of the raw materials and the quality of mixing. Mixing of small amounts of specific raw materials, such as fining agents, coloring/decoloring compounds or cokes, to the bulk of the batch is carried out just before delivery of the batch to the furnace to prevent segregation. Different types of batches use different mixers. For instance, high-silica glasses such as soda-lime, borosilicate, and aluminosilicate are mixed in pan-type mixers with vertical stirrers. The batch is first dry-blended, followed by addition of a small amount of liquid (up to 3 – 4 wt % water or oil) for wet blending. The whole operation takes 3 – 8 min; longer treatment may result in segregation. A typical batch size may be a few hundred up to 4000 kg of material.

Many speciality glasses, especially those with high-density components such as PbO, were once mixed either in muller-type mixers or in horizontally rotating drums, but these mixers lead to segregation due to free-fall movement. High-intensity mixers with vertical stirrers are now commonly used. Wet mixing and batch agglomeration-pelletizing, briquetting or compaction are becoming popular for several reasons, one of which is the avoidance of dust formation, especially during preparation and transport of raw materials containing hazardous components like lead and arsenic-containing batches. Other reasons are prevention of carry-over in the furnace, absence of segregation, and hence better homogeneity, which improves glass quality. Radiative heat penetrates pelletized material faster than batch blankets containing normal raw materials, the single grains in the pellets are bound to the other grains, increasing reactivity during the fusion processes. The use of pellets lowers the energy demand of the glass furnace or allows higher melting loads in a glass furnace.

Cullet is generally added to the mixed batch just before mixer discharge. Sometimes the cullet or the cullet plus normal batch is preheated by raw material preheaters using the flue gas heat contents.

5.2. Melting Units

Most glass is produced by continuous melting processes. Only glasses with special characteristics are manufactured in batch-type processes, which allow greater compositional flexibility. Small production sites manufacturing lead crystal or art glasses often use batch-type processes such as pot furnaces. The function of glass furnaces is the conversion of raw materials into a

homogeneous melt, free of inclusions. In the furnace chemical reactions between batch components leading to fusion and melting takes place. Complete melting is necessary to produce a glass without batch stones. The dissolved gases and gas bubbles should be removed from the melt and the melt homogenized, because small difference in chemical composition cause variations in refractive index or lead to thermal stresses in the final products.

5.2.1. Flat Glass and Container Glass Tanks

Volume production of technical glass is carried out exclusively in rectangular, relatively shallow glass tanks, capable of holding up to 1200 t of melt. The tank functions as a rectangular melting crucible, directly heated from the top by flames or in the melt by electrodes. Convection in the melt mixes the heated surface of the glass melt with the rest of the melt.

The tank is covered at the top by a vault (arch) of silica bricks, known as the cupola or crown, supported by sidewalls which are constructed from different materials: refractories for high temperatures at the inside and insulation bricks or mats at the outside. The total thickness can be 600 – 800 mm. The crowns are constructed mainly from silica or mullite ($Al_6Si_2O_{13}$), but in some cases fusion-cast refractories are used. For the inner layers of the sidewalls, fused-cast alumina – zirconia – silica (AZS) refractory materials and, for some furnaces, chromium oxide refractories are used. The outer layers provide thermal insulation to the furnace.

The melting tank is divided into two sections by a permanent bridge wall or by floating refractory baffles. The larger section into which the fill (i.e., batch plus cullet) is charged by means of the batch house – a small extension (called doghouse) of the furnace in the backwall – is called the *melting end*. The batch plus cullet floats on top of the melt as a blanket or as batch islands. The batch blanket is continuously fed by new raw materials and extends several meters into the melting end. The other separated section of the tank, in which the melt starts to cool and to condition toward its uniform working viscosity, is called the *working* or *refining end* (refiner). Partitioning of the tank into two parts allows continuous production of glass. The working and melting ends are connected by a neck (large float glass furnaces) or a throat. Most container-glass and tableware furnaces are designed with a throat, a covered channel through which the melt flows from the melting end into the bottom section of the working end. In furnaces with a neck, the glass melt flows into the working end without a contact with refractories at the surface. Some furnaces with a direct connection between melting end and refiner use a skimmer to prevent the flow of surface glass that differs from the bulk glass or to prevent the surface scum to flow into the refiner tank.

The melting tank depth is generally 50 – 150 cm, depending on the transmission of thermal radiation from the flames in the combustion chamber on top of the tank to the molten glass. The melting tank design depends also on the glass composition, melting rate, type of fuel and oxidant (air or oxygen), and production rate. Tank parts that come in contact with the melt are usually made of highly refractory fusion-cast AZS or chromium oxide blocks. A typical Siemens-type side port fired continuous tank is shown in Figure 31.

Figure 31. Fossil fuel fired Siemens-type regenerative furnace for container glass production

The conventional side-port regenerative furnace shown in Figure 31 is equipped with two regenerator sections on each side. Each regenerator is connected to the furnace by four to seven ports. During a period of 20 – 35 min ambient air is conducted to the left-hand regenerator for preheating. The hot air (1100 – 1300 °C) flows through the ports into the combustion chamber

of the furnace. In the combustion chamber air is mixed slowly with fuel oil or natural gas injected by one to three lances per port. The mixture produces a flame with a maximum temperature of about 2000 °C in this furnace type.

Figure 32. Top-view schematics of fossil-fuel-fired tank furnaces
A) Cross-fired regenerative furnace; B) End-port furnace with regenerators at the backwall; C) Recuperative furnace with a flue gas/air heat exchanger; D) All-oxygen-fired furnace (without preheating of oxygen)

After 8 – 12 s, the gases exit the furnace and heat the opposite regenerator chambers. After 20 – 35 min, the air and fuel flows are switched, and the preheated regenerator on the right-hand side is used to heat the combustion air. Thus air, flames, and flue gas flows are reversed every 20 – 35 min. By this method about 45 – 50 % of the energy content of the fuel is transferred to the melt for heating and fusion reactions. In direct-fired glass melters without air preheating, the combustion air energy efficiency is much lower.

Schematics of other furnaces in top view are shown in Figure 32.

In the recuperative furnace the flue gases preheat the air in heat exchanger type recuperators; the flue gases are cooled from about 1250 – 1300 to 800 – 900 °C, and air is preheated to about 750 °C. The furnace is often constructed as a unit tank (simple rectangular tank shape) furnace. Similar furnaces but without recuperators and special burner designs are used for all-oxygen-fired tanks, which have been replacing some of the larger air-fired regenerative and recuperative furnaces since 1991.

Some glass melting tanks are provided with electrodes to boost the energy supply to the melt. Forced bubbling improves mixing and heat transfer into the melt. Short cut melt flow along the bottom of the tank prior to its exiting through the throat or neck can be suppressed by a weir or dam, the refractory material of which must withstand high temperatures and glass-melt velocities. Molybdenum-reinforced AZS weirs and chromium oxide refractory walls are sometimes used.

Some tanks are equipped with a section called a deep refiner, which is much deeper than the first part of the melter. The deep refiner allows the bubbles to be more efficiently removed from the melt. The deep refiner is connected to the working end by a throat. In most cases the first section of the melting tank and the deep refiner are separated by a flow barrier. Special furnace designs are often patented by specialized glass furnace construction companies.

Optimum tank design is still being studied. Simulation models are based on three-dimensional finite-element numerical procedures (Computational Fluid Dynamic codes). Numerical models are based on conservation of mass, energy, momentum, and electric charge or potential. The models predict heat transfer, melting rates, temperatures and glass melt flow patterns in the tank. Some models also include

the combustion process and heat transfer in the combustion chamber. The results of such calculations for the temperature distribution in a rectangular glass tank with a combustion chamber on top are shown in Figure 33. A review of the status of computational techniques applied to tank design and a comparison of different models is given in [137].

Important in glass furnace design is a melting tank with extra means to improve heat transfer and which shows a good melting, fining, and homogenization performance. Short-cut flow patterns along the relatively cold bottom should be avoided, and separation of a first loop and a second convection loop in the melting tank may be essential for obtaining a sufficiently degassed and homogeneous glass melt. Numerical glass-tank models can be used to find the optimum furnace design or process conditions with respect to stability, glass quality, energy efficiency, and emissions [138].

Producers of flat glass use the largest tanks with surface areas of 400 – 800 m^2. The fill is distributed evenly over the full width of the tank by auger screws in barrels through multiple openings in the back wall, by pusher bars, or by vibratory plates. The last two methods often act in concert to form a blanket fill across the rear of the melting-end surface. A refractory extension of the melting end, called the *doghouse*, is frequently used to fuse the fill before it moves into the melting end itself. Container-glass tanks are smaller, with melting end surface areas up to 140 m^2, and often no blanket fill is used. Most container-glass furnaces are constructed as end-port-fired regenerative furnaces, and one or two screw feeders in small extensions of the sidewall(s) supply the batch to the top of the melt. The batch generally floats on top of the melt as small islands that together form a caterpillar-shaped batch line.

In sufficiently wide cross-fired tanks, cross-firing ports in the sidewalls are connected to regenerator chambers. In smaller tanks, the ports are usually in the backwall; these types of furnaces are called end-port-fired or U-flame furnaces. Regenerator chambers, which operate in pairs, are used to economize on fossil fuel by extracting heat from the flue gas before it is emitted through the stack. In U-flame furnaces, the strongly elongated flames make a U-turn, and the exhaust port and air inlet port are both in the backwall.

Temperatures up to 1400 – 1600 °C, may be required to melt the fill and to remove the gas bubbles from the melt, depending on the type and quality requirements of the glass. The temperature limit of a tank is determined by the quality of the superstructure material and the melt-line attack (i.e., increased wear of the refractory at the contact refractory – melt – furnace atmosphere). The weakest points that determine the lifetime of a glass-melting furnace are the throat, the refractories at the melt-line positions, and sometimes the crown and the regenerators. Carbon dioxide from carbonate-containing batch ingredients together with water and air trapped in the interstices of the fill, produces an initially foamy melt. Temperature profiles along the length of the tank are controlled to ensure that all batch material is dissolved in the fresh melt and that fining agents remove gaseous inclusions before the glass passes into the refining end of the tank. In some furnaces the surface of the melt (containing scum or foam) in the melting end is skimmed off by floating baffles. In most tableware, container-glass, and lighting-glass furnaces, the melt exits the tank or refining end through a throat in the solid bridge wall.

The principal working characteristics of glass melting tanks are melt efficiency and energy consumption, which depend on the glass type. For float glass a specific load of 1.5 $t\,m^{-2}\,d^{-1}$ of melt and 6500 kJ/kg of glass melt are typical; for container glass 2.5 – 3.5 $t\,m^{-2}\,d^{-1}$ of glass can be melted with a specific energy consumption, depending on cullet ratio in the batch, of 3600 – 5.000 kJ/kg. Higher energy requirements (8000 kJ/kg) and lower specific melting loads ($< 1.5\,t\,m^{-2}\,d^{-1}$) have to be accepted for TV panel glass because of the required high quality.

Enlarging and locally deepening the tank increases the allowable throughput, especially for colorless glasses. Additional heating by electrodes is required for deeper tanks. Applying an a.c. voltage between molybdenum or tin oxide electrodes in the melt generates heat in proportion to the square of the electric current and the glass melt resistance. Bubbling air or steam helps to achieve an even bath temperature and the extra mixing provides a better homogeneity.

The life span of a tank depends on the quality of the refractory bricks. Modern container-glass

Figure 33. Temperature contours calculated for a end-port-fired regenerative container glass furnace. The surface temperatures and cross-section temperatures along the length axis are presented. Red: $> 1450\,^{\circ}\mathrm{C}$, blue: $< 1350\,^{\circ}\mathrm{C}$. The initial part of the flames calculated by the simulation model is also shown.

tanks are designed to be used for six to eight years before rebuilding is necessary. Float-glass furnaces producing the melt to be shaped as flat glass reach lifetimes up to 13 years before rebuilding.

5.2.2. Unit Melters

Recuperatively fired unit melters are used for continuous production of high-quality optical or ophthalmic glasses, soda-lime glasses for drinking bottles, and glass fibers or opal glasses. Often, typical tank dimensions are small: 2 – 5 m wide, 10 – 12 m long, containing 4 – 100 t of melt. Larger melters are generally designed as regeneratively fired furnaces or as oxy-fuel fired melters, but recuperatively fired unit melters with production rates of up to 150 t/d exist.

Some unit melters are directly fired without any air preheating, but they have a very poor energy efficiency and very low melting loads. Today, directly fired furnaces are only used in developing countries. In recuperatively fired and directly fired unit melters the combustion air and fuel are premixed in small burners and the flames cover the glass-melt surface. Firing temperatures of at least 1600 °C can be reached by positioning the burners opposite each another or in staggered arrangement. The specific melting loads barely exceed values of $1.5\,\mathrm{t\,m^{-2}\,d^{-1}}$. Low heating efficiency and higher operating costs offset the lower capital investments of unit melters compared with container- and flat-glass tanks. Unit melters are economical only in processes that require fairly small quantities of glass or rapid changes in glass composition.

5.2.3. All-Oxygen-Fired Melters

Improvements in the technology for separating oxygen from air by cryogenic or selective gas absorption techniques in the 1980s and 1990s and strict emission limits for nitrogen oxides justified the use of oxygen instead of air for the combustion of fossil fuels in glass furnaces in numerous glass-melting operations in the United States, Central America, South America, Korea, Japan, and Europe. Instead of preheated air, pure or almost pure oxygen is used as oxidant for fuel combustion. The furnace atmosphere is amost free of nitrogen, whereas air-fired furnaces have nitrogen concentrations of about 65 vol %. The volume flows of flue gases are only 15 – 25 % of those of similar air-fired furnaces. These much lower volume flows of hot flue gases result in much smaller energy losses than in air-fired furnaces. Due to the low volume flows and the risks of preheating oxygen, the flue gas heat is not recovered. Only in a few cases the flue gases are used to preheat part of the batch.

Most oxygen-fired melters are constructed similarly to unit melters. Generally, three to five burner blocks are installed in each sidewall. Typical oxygen burners have separate nozzles for

oxygen and for atomized fuel oil or natural gas. The luminescence of the flames can be improved by delayed oxygen – fuel mixing, which creates soot particles. The furnace atmosphere contains high concentrations of volatilized components from the batch blanket and glass-melt surface. Precautions must be taken to protect the combustion chamber refractories from the aggressive vapors.

Oxygen-fired furnaces show low energy consumption, although the energy requirement for the oxygen production also must be taken into account. The nitrogen oxide emissions and particulate emissions are generally lower compared to air-fired furnaces [139]. Specific melting loads of up to 2.5 t m^{-2} d^{-1} for oxygen-fired container-glass furnaces are feasible.

5.2.4. Electrical Melting Units

In some countries, all-electric melting in glass furnaces has become a leading objective for economic and environmental reasons. The method is based on the electrical conductivity (Joule heating) of a melt. Electrical conductivity increases as a function of temperature. The conductivity is caused by the presence of mobile alkali and alkaline earth metal oxides in the glass. Low-frequency (50 – 60 Hz) alternating current is used to minimize energy dissipation resulting from the activation energy required for electrical conduction.

The all-electric vertical melter is charged from the top, and the fresh batch layer covers the complete melt. Because of the relatively cold batch on top, these melters are also called cold-top electric melters. The crown or roof of the furnace is also relatively cold. Most vapors from the hot melt are entrapped in the batch layer, unless part of the melt is not covered, and therefore emissions of these melters are very low compared to fossil-fuel-fired melters with uncovered glass melts. For example, in an air-fired furnace up to 40 % of the fluorine evaporates and is lost, compared with only 2 % in an electric melter. Especially for glass or batch compositions containing volatile or environmentally hazardous volatile components an all-electric cold-top furnace offers an environmentally sound alternative. Production is usually limited to small charges of 4 t/d, although larger units with 120-t/d capacity also exist.

Molybdenum, tin oxide, sometimes graphite (under reducing conditions), or platinum electrodes extend from the bottom or well into the melt. A cold-top furnace is shown in Figure 34.

Figure 34. Cold-top electric glass melting tank
a) Blanket of batch; b) Melt; c) Molybdenum liner (not always necessary); d) Molybdenum pipe or refractory canal; e) Riser; f) Forehearth/working end; g) Electrodes

Electrodes can extend through the bottom as vertical rods, horizontally through the sidewalls, or can dip into the melt through the batch blanket. During the heating phase, burners are used to bring the cullet or batch in the furnace up to temperatures at which the electrical resistivity of the melt becomes low enough to conduct electric current. The burners are then removed, and the electrodes provide all the energy required for melting, fining, and homogenization. Controlled convection of the melt is important to obtain a homogeneous melt and to avoid short-cut flows.

An additional advantage of electric heating is the control of glass composition, especially when using volatile components, which is particularly useful in the production of certain optical glasses. Controlling the reaction between the batch blanket and molten glass in the reaction zone is of special importance. First a melt of the low-melting components is formed, and the refractory batch components dissolve in these primary melts. Just after melting, in the hottest zones, the fining process occurs. Bubbles are released from the melt and escape through the pores in the batch blanket. In cold-top electric melters gases released from the melt must find a way through the fill. Because of this and the

possibility of fresh cold dense melt flowing directly to the bottom of the tank, the fining process can sometimes become critical and unstable. The molten glass flows from the melting end through a throat or canal into a riser and into the working end.

Production of optical glass represents the epitome of criteria for glass homogeneity and freedom from flaws. Platinum crucibles are used to produce blister-free glass at a temperature up to 1550 – 1600 °C. The platinum-covered vaults of the melting section are usually made of zircon or silica bricks, depending on the type of glass being produced. Older burner systems have been replaced by environmentally safer platinum, tin oxide, or molybdenum electrodes.

Electrical melting has some disadvantages, including the higher energy cost, which is only partly offset by the lower amount of energy required (2500 – 4000 kJ per kilogram of glass), and the more rapid decrepitation of the refractory material compared to conventional units. Hence, the working life of a typical cold-top electric melter is only about 50 % of that of the lifetime of regeneratively fired glass melting tank furnaces. The advantages, such as small units, low capital investment, flexibility in types of batch materials, small vaporization loss of expensive or environmentally hazardous components, no nitrogen oxide emissions in case of raw material batches without nitrates, and particularly environmental compatibility, make resistance heating by electrodes sometimes an attractive proposition.

5.2.5. New Melter Designs

An overview of alternative melting technologies is given in [140]. Most alternative melting methods have separate sections for melting, degassing/fining, and conditioning or homogenization. The melting zone can even be divided into a batch preheating area, a primary melting stage, and a final melting and firing stage.

Some new concepts use subatmospheric-pressure fining to enhance bubble and gas removal from glass melts, and some melters use centrifugal forces to separate the gaseous inclusions from the molten glass.

A combination of batch preheating, firing at low temperatures to reduce NO_x formation, and separate zones for melting, fining, and refining and conditioning is presented by the LoNOx Melter developed in the mid-1980s in Germany (Fig. 35) [141].

Figure 35. Design of the Sorg LoNOx melter for container-glass melting

5.2.6. Pot Furnaces and Day Tanks

Pot furnaces are scaled-up research furnaces. The name derives from the use of monolithic high-quality clay pots to contain the molten glass. Generally, the freshly prepared pots are tempered slowly at 900 °C by electric heating, prefired at 1200 °C, and fired to obtain a dense low-porous material at about 1400 °C in the pot furnace itself. Most pots are made of aluminum silicate materials. Open pots containing 150 – 1000 kg of melt are still used in Europe to manufacture colored and optical glasses as well as crystal glass. Typical areas in Europe using pot furnaces for art glass or crystal glass are the Venice area (Murano island) in Italy, the South of Sweden, the Czech Republic, the Bavarian forest in Germany, and some areas in Portugal, France, and in the vicinity of Birmingham in the United Kingdom. Closed pots surrounded by refractory brick walls were the preferred setup in the United States. The largest pot furnaces contain eight to ten pots, each with a diameter of about 0.7 – 1 m. Today, pot furnaces are hardly used in the United States because of their low energy efficiency and operational fluctuations, which can lead to variations in glass quality. Only for small production sites manufacturing handmade glass objects, pot furnaces are still applied.

The type of batch and glass specification determine the manner in which the pots are used. A typical melt cycle for crystal glass production in a pot furnace takes about 17 h and entails the

following: 6 h to melt the first fill, 2.5 h melting after addition of a second batch, 7 h melting and fining after adding a third batch at the highest temperature level close to 1350 – 1400 °C, and finally a lower temperature stage for 1.5 h to refine and condition the melt. The working temperature at which the glass melt is collected from the pot for forming processes depends on the glass composition and is in the range of 1100 – 1200 °C.

Production of specialty, high-value products (e.g., specially colored glass) or enamel glass frits is often carried out in day tanks. These tanks, usually built from refractory bricks, are typically heated rapidly by one to three pairs of oil or gas burners and produce 1 – 5 t/d of glass. The glass melt depth is only 10 – 20 cm. These day tank furnaces are particularly well suited for the manufacture of soft (i.e., low-viscosity) glass, such as crystal or soda-lime glass, which requires special production techniques. They are not as well suited for the manufacture of low thermal expansion borosilicate glasses because of the high boron loss during rapid heating. Such glasses can be produced if less rapid heating is used, with an increase in the average melting and fining time to 48 h. Even then, silica-rich stones, crystals, or cords, resulting from loss of sodium or boron at the surface of the melt, may still be found in the glass.

5.3. Melting, Fining, and Homogenization

The three steps involved in the production of a glass melt are melting, fining, and homogenization. The cold batch is charged to the tank or pot and melted at 1200 – 1650 °C, depending on the type of glass. Decarbonation and dehydration are the first chemical processes to take place in the batch, followed by partial melting and sintering as the eutectic temperature of some batch components is reached. Several new crystalline phases can be formed, and depending on the temperature ranges, can melt or dissolve in eutectic melts. Some of the sulfate, almost all carbonate, and water are removed from the melt. The primary melts containing the alkali metal oxides (sodium and potassium, sometimes lithium), alkaline earth metal oxides (mainly calcium and magnesium), or boron components act as fluxes that dissolve the refractory batch components. Gas solubility in the melt decreases with increased dissolution of the refractory components, leading to bubble trails. The bubbles contain CO_2, N_2, O_2, SO_2, Ar, water vapor, or combinations thereof.

Dissolution of refractory batch components, the most important being coarse sand grains and alumina raw material, slows down as the melt becomes nearly saturated, and a viscous melt with only a small fraction of nonmolten material appears at ca. 1150 – 1250 °C. The remaining refractory batch components will dissolve at further temperature increase. The batch slowly becomes transparent but remains chemically inhomogeneous. Blisters (bubbles) and cords (inhomogeneities in the melt) are particularly prominent at this point. Removal of dissolved gases and bubbles and finally resorption of residual seeds (small bubbles < 0.2 mm) characterize the next stage. The rate of melting depends on batch composition, particle-size distribution, temperature, and amount of cullet used.

The removal rate of gases from the melt depends on the kind and amount of active fining agent added to the batch and the redox state of the melt, which often determines the temperature of fining-gas release and the quantity of gas produced by the fining agent. These gases will diffuse into small seeds, which grow due to this gas infiltration. The bubble ascension rate in the melt is proportional to the square of the bubble diameter. The dilution of the gases in the bubble with fining gases cause not only the fining gases but also the other dissolved gases in the melt to diffuse into the growing bubbles. Fining gases include sulfur dioxide, oxygen, and sodium chloride vapor. During cooling of the melt the residual fining gases can be resorbed by the melt, since their solubility increases with decreasing temperature.

Blisters, seeds, and cords, already detectable by refractive index variations of around 5×10^{-4}, are removed in the fining and homogenization stage. Blisters and seeds are ≥ 0.2 and 0.2 – 0.05 mm in diameter, respectively. The use of fining agents is reviewed in [126]. Considerable attention is required in glass manufacture to make the melt blister-free by both expulsion of gas bubbles (fining) and subsequent resorption of residual small seeds during controlled cooling of the melt (refining). Blisters can arise

from several sources, including the type of raw material used, the tank atmosphere, reactions in the boundary layer between melt and refractory lining, electrochemical reactions in electrically heated furnaces, electrochemical reactions in refractories containing polyvalent ions such as iron and titanium, air seeping through the tank structure, or mechanical operations (e.g., stirring or gobbing). Methods for fining are:

- Addition of chemical fining agents to the batch
- Raising the tank temperature, with attendant decrease of melt viscosity and increase of bubble expulsion
- Lowering the temperature in the working end and thus increasing gas resorption

Homogenization is carried out by:

- Blowing air or water vapor into the bottom of the tank through bubbling pipes.
- Mechanical stirring or acoustic homogenization.
- Applying a certain temperature profile in the combustion chamber along the length of the furnace. A hot spot in the central part causes free convection flows in the melt and thus improves mixing and heat transfer. A well-developed spring zone in the central part of the tank may prevent short-cut glass-melt flows along the relatively cold melting tank bottom.

Sodium sulfate and arsenic and antimony oxides are generally used as fining agents. Only the pentavalent arsenic and antimony compounds produce oxygen as a fining gas at high temperatures. Therefore arsenates or antimonates are used in the batch, or nitrates are added to oxidize the trivalent arsenic or antimony compounds during melting. Nitrates produce oxygen between 500 and 900 °C [142]. Antimony oxide, in combination with arsenic trioxide and nitrates, is used in the production of optical glasses. Other, less important fining agents include fluorides and, more rarely, chlorides and bromides. Typically, ca. 0.3 – 0.6 wt % arsenic oxide or arsenates is added to the batch, although for some glass types up to 1.5 wt % arsenic trioxide may be employed. Antimony fining is used for TV panel glass compositions and for sulfate-free soda-lime glasses. Arsenic trioxide plus nitrates or arsenates is a widely used fining agent for lead-containing glasses that are melted under strongly oxidized conditions to avoid formation of lead metal.

Above about 1350 °C As_2O_5 in the melt decomposes into As_2O_3 and oxygen, which is the fining gas. During cooling below about 1300 °C the reaction is reversed. The fining mechanism with antimonates is similar, but the pentavalent antimony species dissolved in the melt decompose at lower temperatures than As_2O_5, and oxygen is released above about 1250 – 1300 °C, depending on the redox state (oxygen fugacity) of the melt. An additional advantage of arsenic or antimony is that oxygen gas bubbles which do not combine with ambient gas bubbles in the melt are resorbed at lower temperature because of the back reaction from arsenic trioxide to arsenates or antimony trioxide to antimonates.

The low price of sodium sulfate makes it attractive as a fining agent in commodity glasses. It is, however, soluble only to ca. 1 wt % in most melts and may lead to foaming or even sodium sulfate droplets (sulfate gall) in the glass product if used in excess. Sodium sulfate in oxiding melts decomposes at above 1350 – 1450 °C to give SO_2 and O_2 as fining gases. During cooling, bubbles containing both oxygen and sulfur dioxide can be resorbed. In reduced molten glasses, sulfates react with reducing agents to give SO_2 gas at temperatures just above 1000 – 1100 °C. This SO_2 gas is the major fining gas in these glass melts. Resorption of SO_2 bubbles in the absence of oxygen is limited, and only in strongly reduced melts can SO_2 or S_2 bubbles be resorbed due to formation of S^{2-} in the melt. The oxygen fugacity of the melt determines the temperature at which sulfates start to decompose, and the amount and kind of released gases also depend on the redox state of the batch and melt.

5.4. Energy-Saving Technologies

The melting process requires relatively large quantities of energy. The costs of energy contribute 12 – 15 % to the total glass production costs, depending on the country and type of glass. Only about 25 – 55 % of the energy added to the furnaces is used for heating the raw material and for the endothermic reactions involved in fusion of the raw materials into a melt. The most important energy savings to be achieved

in industrial glass melting and glass production focus on:

1) Improvement of the thermal insulation of glass furnaces by using high-quality refractory materials for the glass-melting tank and superstructure, allowing higer temperatures inside the furnace.
2) Combustion control to avoid excess air in the combustion chamber.
3) Reclaiming of energy from the waste gases by extra air preheating or batch or cullet preheating. In Western Europe some container glass furnaces are equipped with cullet preheaters or mixed cullet/raw material preheaters, which recover 10 – 20 % of the energy from the gases and return it into the furnace. There are different types of batch/cullet preheaters: direct contact preheaters (no physical separation between flue gas and raw materials); indirect contact preheaters (different channels for flue gas and raw materials), and cullet preheaters with electrostatic fields for capturing flue gas dust particles.
4) Using oxygen instead of air, which reduces the flue gas volume flow.
5) Improving control of glass melt viscosity in combination with new forming techniques to manufacture lightweight glass products.
6) Application of new furnaces, improving the heat transfer to and in the glass melt (e.g., Sorg LoNOx melter).

5.5. Glass Cooling

During cooling, a melt is transformed from a viscous fluid into a viscoelastic material and eventually into a brittle substance. These gradual transformations are accompanied by large changes in properties.

High residual stress can be generated during the transition from a melt to a cooled glass. The magnitude of such stresses depends largely on the cooling rate within the temperature range of the transformation from a liquid into a rigid state, the coefficient of linear expansion of the glass, the thickness of the glass, and the glass homogeneity. Annealing by controlled cooling between the so-called annealing point (viscosity $10^{12.4}$ Pa · s) and strain point ($10^{13.6}$ Pa · s) reduces residual stress to an acceptable level. The *upper stress release temperature* (Section 4.1.1) corresponds to a glass viscosity of ca. $10^{12.4}$ Pa · s or a stress release time of 15 min with a gradient of 40 °C/min. *The lower stress anneal* temperature (strain point) corresponds to a viscosity of $10^{13.5}$ Pa · s or a stress release time of 15 h.

Determination of the time required to release stress at a certain temperature requires measurement of the viscosity. This is not practical in the region of the stress release temperature. In practice, stress in the cold glass is measured optically as the retardation of polarized light in a stressed medium and expressed in units of nanometers of retardation per centimeter of material.

Glass is amorphous and therefore isotropic; its properties are often the same in all directions. However, under compressive or tensile stress anisotropic behavior appears, and the glass becomes birefringent. The applied stress deforms the polarizable (an)ions within the glass (prestressed electron cloud), which results in a different velocity of light transmission in one polarization direction as opposed to the other. A phase shift D appears, depending on the glass thickness and the stress present. This phase shift is is generally expressed per unit of glass thickness; usually 1 cm: $D/d = C \cdot s$, where D is the phase shift in nm, s the stress in Pa, C the stress-optical coefficient or Brewster's constant, and d the glass thickness in cm. Some values of C (in nm cm^{-1} Pa^{-1}) follow:

Soda-lime glass	0.27
Borosilicate glass	0.40
Quartz glass	0.34
$3\,PbO \cdot 5\,SiO_2$	0

Due to this birefringence phenomenon, stresses in glass can be measured by using a polarizing microscope. Monochromatic light is polarized by a polarizer. Because polarizer and analyzer are perpendicular to each other, no light is transmitted. When a birefringent material is placed between polarizer and analyzer at an angle of 45°, the two components of the beam of light – one parallel and the other perpendicular to the stress direction – are transmitted with different velocities through the material (retardation of polarized light in the direction of compressive stress), resulting in a difference in phase. Then

after passing through the sample, the two light beams interfere with each other. If the phase shift is equal to $1/2\lambda$, $(1 + 1/2\lambda)$, etc., the composite beam vibrates in the direction of the analyzer and therefore is transmitted. If the phase shift equals λ or a multiple thereof, the composite beam vibrates perpendicular to the analyzer and is extinguished. The stress release viscosity is determined from the required stress retardation time t by using the following formula:

$$D_s = D_0 + CA^{-1}t^{-1}$$

where D_0 is the original retardation caused by the stress, and D_s the retardation after time t, both expressed in nanometers per centimeter; A is the cooling constant; and C is the Brewster constant of the glass.

Residual stresses, expressed as maximum retardation of polarized light in the stressed glass, of the order of 100 – 200 nm/cm remain in the glass after cooling. The geometry of the article and glass composition affect the cooling process and hence the amount of residual stress. Tableware is cooled at such a rate that residual stress is less than 50 nm/cm; optical glass requires slow cooling to keep residual stress below 10 nm/cm. Figure 36 shows a recommended temperature – time curve for the cooling of a glass article.

Figure 36. Annealing and cooling of a glass article (tube) with a diameter of about 10 cm and a wall thickness of 1 cm The annealing temperature is about 530 – 540 °C, and the strain point about 500 °C

5.6. Heating and Regulating Glass Melts

Natural gas, fuel oil, or electricity is used in most glass melting units. Radiation directly emanating from the flame and reflection from the crown into the melt are the principal processes of heat transfer in fossil-fuel-fired melters. Iron in the glass, especially in the iron(II) state, increases the IR absorption and the transparency of the melt for IR radiation decreases with increasing content of iron(II). Glass melts for products like tinted float glass and green or amber container glass show limited transmission of the IR radiation from the crown and flames. Extra convection or electric boosting in these glass melts is necessary to provide heat to the bottom section of the melting tank. Production of glass that absorbs strongly in the infrared requires a shallow bath, electrodes, or bubbling to maintain a sufficiently high temperature at the bottom of the pool.

Preheated air is injected into the combustion chamber in most furnaces. Both recuperative and regenerative preheating can be used. *Recuperative preheating* entails countercurrent or cocurrent heat exchange from the flue gases to the combustion air in a metal heat exchanger, the so-called recuperator. Often the flue gases flow through the core of the recuperator while air flows through the mantle of the twin shell recuperator or through tubes positioned in the flue gas channel of the recuperator. About 25 – 35 % of the flue gas heat can be transferred to the combustion air in such recuperators. Small glass tanks and tanks used for glass-fiber manufacture tend to operate with this system.

Regenerative preheating involves a discontinuous process that originated in the steel industry. Here, air is blown before combustion through a refractory brick chamber, which is itself heated by the flue gas. In this cyclic procedure, during a period of 20 – 35 min air is preheated to 1200 – 1350 °C in one regenerator, and the flue gases preheat the bricks (piled as a checkerwork) in another regenerator at the same time. The exhaust gases are cooled from about 1450 to 550 °C, transferring about 60 – 65 % of their sensible heat to the refractory bricks. After this period, the preheated regenerator is used for combustion air preheating, and the other regenerator is heated by flue gases.

The temperature in the melting tank and in the refractory walls is measured by Pt – Pt – Rh thermocouples embedded in zircon, AZS, or chrommium oxide refractory blocks and positioned about 5 cm deep in the vault of the tank. Some

thermocouples are positioned in the melt, for example, just before the melt enters the throat. Ideally, this temperature is constant and must be controlled; the set point for this thermocouple depends on melting load and glass color.

Thermocouples in the refractories of the crown or positioned in the combustion chamber just below the crown measure the combustion chamber temperatures, and temperature profiles in the combustion chamber are controlled to avoid damage to the crown and to achieve the required temperature profile in the melter.

Optical pyrometers are used to measure temperature along the walls of the tank or the temperature of the metal-line. Melt viscosity is not monitored but inferred from the estimated melt temperature, although some feeders are equipped with on-line viscosimeters to control glass melt viscosity prior to delivery to the forming process. Platinum-sheathed thermocouples are used in the melting end and before the melt enters the forming cycle. The temperature of the regenerator is also monitored with thermocouples. Tank pressure is kept within ± 0.04 kPa of ambient pressure and is measured by metal membrane manometers located below the furnace in the superstructure. Flue gas blowers or valves are used to control the pressure. To avoid leakage of flames or gases to the ambient air through the joints, a furnace pressure slightly lower than ambient pressure is preferred.

Sensor electrodes, optical laser reflection systems or nuclear radiation level devices measure the glass melt level. Changes in glass melt level are corrected by changing the batch charging rate.

The four principal variables that must be monitored during melting are the flows of natural gas or fuel oil and combustion air, batch charging rate, and temperatures in the melt and combustion chamber, all of which are kept constant for specific melt and fining temperatures. Standard technical gas analyzers or zirconia/platinum-based oxygen activity sensors are used to control the intake of fresh air and the composition of flue gases.

5.7. Refractory Lining of Melting Units

The three criteria for selecting refractory materials are: required lifetime, potential glass defect rate, and cost per amount of glass produced. To obtain an idea of the amount of refractory material required, consider a medium-size, 130-t/d tank with regenerative heating. Construction of such a tank requires 460 t of fire clay, 175 t of fused-cast tank bricks, 104 t of chrome magnesite ($MgO \cdot Cr_2O_3$) or magnesia – alumina spinel refractories, 112 t of magnesite or forsterite (Mg_2SiO_4) bricks, 100 t of silica bricks, 9 t of zircon ($ZrSiO_4$), and 2 t of unspecified lining material. Tank blocks poured from refractory melts are increasingly used as lining material in large glass tanks to improve contact between melt and lining material and to prevent problems with stones and cords in the final product.

The most widely applied refractory material for glass melting tanks is fused cast AZS produced from a melt of alumina, zircon (zirconia silicate), and small amounts of fluxing agents like soda. The AZS melt is poured in sand molds at temperatures exceeding 2000 °C. The sand molds containing the cast material are cooled very slowly to avoid thermal stress and formation of cracks. The refractory fused cast blocks must be post-treated to achieve the desired dimensions and to remove parts which contain voids caused by contraction during cooling.

A more recent development is the use of fusion-cast 96 % ZrO_2 blocks, a refractory material more expensive than conventional blocks. These are used only in those parts of the tank that are particularly susceptible to corrosion. The use of these blocks in melting tanks for the production of high-quality glasses like TV panel glass reduces the defect level in the final products.

Chemical considerations limit the choice of lining material. The most common materials used are silica, alumina, or zirconia, or combinations thereof. Linings containing sintered chromium oxide are used in the production of some specialty glasses like E glass for continuous filament fibers. The high price of tin oxide prevents its use in normal applications. Magnesium oxide dissolves in the glass melt and can therefore only be used in the regenerator or parts of the combustion chamber.

The crown of most glass furnaces is made of silica with very low amounts of residual quartz and with > 97 wt % SiO_2. For higher crown temperatures or aggressive gas atmospheres, the more expensive mullite, AZS (special quality

with a low fraction of silicates), or fusion-cast alumina refractories are used. The sidewalls of the combustion chamber are constructed from fusion-cast AZS, chromium oxide, and sillimanite or mullite for some kinds of glasses. Zircon refractories are applied between AZS and silica to avoid a direct reactive contact between silica and AZS. An overview of the refractory materials used is given in Table 27.

Glass melts tend to wet platinum (electrodes, stirrers, feeder elements, bushings) and molybdenum (electrodes). Caution is needed in using these materials in melts because some glass compositions and low or very high oxygen fugacity will corrode them. The vault of a tank is usually lined with silica, although its chemical resistance is not particularly good in specific temperature regions. The corrosion products of silica are soluble in the melt, however, and hence do not significantly affect melt composition. Melting products derived from silica, especially those resulting from reactions with sodium vapors from liquid sodium silicates, can react with the AZS sidewall refractories forming alumina-rich sodium silicate melts with some baddeleyite (ZrO_2) crystals or dissolved zirconia. These melts dripping into the melting tank can form knots and recrystallized components like secondary baddeleyite in the glass products.

The refractory lining of the tank and superstructure is 250 – 350 mm thick and covered by additional refractory layers. These layers provide thermal insulation, and the requirements are different to those of refractories in direct contact with the melt or furnace atmosphere. Insulating refractory bricks often show a high porosity. Typical insulating refractories are made of aluminum silicates like chamotte and sillimanite. Patch is used to seal the joints to avoid leakage and cold condensation spots. The tank refractories at the position of the metal line are not covered by insulation layers. The refractory blocks at melt-line level are often cooled with air from the outside to reduce the rate of attack by the melt at these positions. Melt-line corrosion is caused by microconvection of the glass melt at the surface due to surface tension gradients of the melt close to the slowly dissolving refractory. Microconvection removes the protecting diffusion barrier formed between the melt and the refractory material. This microconvection becomes slower at lower temperatures.

5.8. Vapor-Deposited Glasses

Vapor-deposited glasses are discussed with optical waveguides (see → Fiber Optics, Chap. 3.5.). The process is also of interest for specialty glasses (for instance for optical fibers) that require extremely high purity or are prone to liquid immiscibility in conventional melting. All vapor deposition processes use volatile halides (e.g., $SiCl_4$ or BCl_3) or metal chelate compounds. Rare earth organic chelates are used as additives in laser optics. These gases/precursors are processed to provide bulk high-purity oxide glasses. The pure halides are entrained in a carrier gas (oxygen) at < 323 K and react at > 1773 K. Reaction of the halide with oxygen results in condensation of a finely divided oxide powder on the substrate. The high-purity, inclusion-free powder has a surface area of about 20 m^2/g, which provides a sufficiently powerful drive for rapid, thermally activated (using flames, microwave, or plasma techniques), viscous sintering. Examples of glasses manufactured in this way are Corning Code 7943 and 7940.

5.9. Occupational Health

The principal health concerns in the glass industry have been reviewed [127–129]. The potential hazards specific to this industry include silica, lead, arsenic, antimony, asbestos, barium, chromium and other heavy metals. Heat stress, noise, and IR radiation must also be addressed. Other factors of concern are particulate and NO_x emissions from furnaces. Firing under reducing conditions may lead to excessive CO formation in the furnace. Most of the CO is oxidized to CO_2 in the flue gases, but those working in the vicinity of poorly sealed furnaces must be aware of health or poisoning risks. Three *control measures* are recommended to deal with the hazards associated with glass manufacture:

1) Engineering controls that include confinement, automation, and isolation in handling raw materials; batch room ventilation; and, whenever possible, substitution of questionable chemicals by harmless ones; batch handling is preferably carried out in closed

Table 27. Refractory materials used in glass furnaces

Refractory	Composition, wt %						Apparent porosity,	Density, g/cm^3	Maximum use temperature,	Linear thermal expansion, %		Use
	ZrO_2	Al_2O_3	SiO_2	MgO	Cr_2O_3	Other	vol%		°C	at 982 °C	at 1316 °C	
Fused cast

spaces with baghouse filters to prevent dusting during filling or discharging of the silos.
2) Administrative controls, including job rotation, education, safety instructions and proper work practices.
3) Use of personal protective equipment, including respiratory protection, proper clothing, and hearing and eye protection.

In the United States, OSHA has established the right of employees to be informed of the potential hazards of materials in their workplace. This organization also requires that producers of hazardous materials determine the potential health and physical hazards of such materials and transmit this information to the consumer. Among the standard reference works on industrial hygiene is *Patty's Industrial Hygiene and Toxicology* [130]. For most toxic components limits have been set for levels in ambient air. Procedures and instructions for handling toxic materials or flammable and explosive components are often part of ISO 9002 or other standardized practices in modern glass factories.

6. Forming

The shape of a piece of hot glass (temperature above T_g) can be changed by an external force which causes viscous deformation. In the known forming techniques the external force is applied by:

- Drawing (fiberglass, flat glass, tube glass)
- Blowing (container glass, bulbs)
- Pressing (tableware, container glass, TV panels)
- Centrifuging (insulation glass wool)
- Rolling (wired glass, figure glass)
- Casting

In some cases, these processes are combined. The degree to which the glass is transformed depends on the magnitude of the force and the prevailing glass viscosity. A low viscosity imparts a high rate of deformation. After the forming process a high viscosity is required, so that the product retains its shape (viscosity of about 10^7 Pa · s, softening point). During forming, the glass should be cooled down precisely to achieve these conditions. The degree of cooling depends on the heat content of the glass product and the rate of production (contact time in the mold). Large products with a high heat content can not be formed as fast as smaller products. Most forming processes take place at a viscosity of 10^2 to about 10^4 Pa · s (working range). The working temperature is defined as the temperature at which the melt has a viscosity of 10^3 Pa · s. During forming, the glass melt cools and the viscosity increases. With increasing viscosity, the required transforming force increases, and the deformation rate will decrease. Viscosities and temperatures for some forming techniques are listed in Table 28.

Table 28. Deformation and forming methods for different glass products

Process	Viscosity, Pa · s	Temperature,∗ °C
Drawing, centrifuging	10^2	1200
Fast pressing	10^3	1050
Fast blowing	10^4	900
Slow pressing	10^5	800
Slow blowing	10^6	750
Form becomes rigid (or stable)	10^7	700

∗ For soda-lime glass.

Most of today's forming methods have their origin in the use of the blowpipe, invented by the Romans and reaching the pinnacle of expression with the Venetian glassblowers of Murano.

Molten glass is pressed, blown, drawn, rolled, poured or quenched, depending on the desired shape and intended use. Bottles, dishes, optical lenses, and television tubes are formed by blowing, pressing, casting, or spinning glass against a mold to cool it and set its final shape. Window glass is made by floating the glass melt on a molten tin bath; tubing rods and optical fibers are made by drawing the glass in air until it sets and can be cut to length. Frit glass, some of which is intended to be crushed into powder, is quenched between water-cooled rollers or ladled directly into water and then dried (dry-gauged). Tube glass is drawn from the melt by conducting the melt through a feeder opening on a sloped or vertical rotating mandrel (blowpipe). The glass distributes itself along the cylindrical surface of the mandrel and is drawn out into a tube. The mandrel consists of a hollow ceramic cylinder through which air is blown. This air flows through the resulting glass tube, which is released from the mandrel. Mandrel

size, air pressure and drawing speed and glass melt viscosity determine the dimensions of the glass tube. Art glass is often hand-formed by free blowing and shaping while soft. These forming operations all require a melt cooled to a characteristic viscosity of between 10^2 and about 10^4 to 10^5 Pa · s, generally at 800 – 1400 °C (depending on glass type), as shown in Figure 13.

6.1. Hand Forming

Some industrial forming methods derive from hand-forming techniques and are therefore discussed in some detail here. The major breakthrough in glass production was the invention of the blowpipe by the Romans. The flexibility of this technique still makes it popular in fabricating complex specialty items. The blowpipe is a hollow stainless steel pipe. A gob of glass is collected at the end of the pipe by dipping it into the melt. Blowing air through the pipe results in swelling of the gob, provided the viscosity of the glass is still sufficiently low, reheating is necessary if the viscosity becomes too high.

The *Rhenian technique* uses a blowpipe with a conically thickened end. The glassblower gathers the appropriate amount of glass melt from the working end of the furnace or the pot and collects the glass on the end of the blowpipe, and the gob is cooled by rotation in a bowl-shaped wooden form or on a metal plate until the viscosity required for blowing is reached. The gob is then placed in an iron or wooden mold and blown to the shape of the mold.

In the *Bohemian technique*, a straight blowpipe is used. A gatherer, who collects the gob on the pipe, and the glassblower work in concert. The gatherer collects a small amount of glass on the end of the pipe and blows a small sphere with dimensions prescribed by those of the final product. The glassblower takes the pipe from the gatherer, dips it again in the oven, collects as much glass as needed for the final product and blows it to the shape of the mold.

6.1.1. Blowing

The hand-forming operations described above immediately suggest a way of automating a glass-forming process by blowing gobs of the proper viscosity into molds. Many products are indeed made by variations on this theme, as suggested by the names of the various techniques: blow, blow-and-blow, puff-and-blow, and press-and-blow processes.

Deep items (e.g., bottles, jars, and light-bulb envelopes) are formed by *blowing* glass into molds with air pressure, as shown in Figure 37. Hinged molds, which can be opened to remove the ware, are generally used for the blowing operation. Articles with circular cross section are blown into hinged paste molds. These molds are lined with a water-absorbent coating or wetted cork, which develops a steam cushion between the coating and glass during blowing, allowing the glass to be rotated in the mold. A second type of mold is the hinged hot-iron mold used for the manufacture of ware with noncircular cross section. Here, the glass comes directly into contact with the mold surface on blowing. The surface quality of articles blown into hot-iron molds is inferior to that of paste molds. Hot-iron molds are used for ware of any shape, in particular for screw threads, multiple decoration, or raised lettering.

B) a) Empty mold; b) Blank ready for blowing; c) Blank blown out; d) Untrimmed piece; e) Finished piece

Narrow-mouth containers are manufactured in a two-stage, *blow-and-blow* process (Fig. 38). The gob is delivered to a blank mold, where a settle blow and a counter blow form it into a blank. This blank is then transferred to a blow mold, where it is blown into its final shape.

Figure 38. Forming by the blow-and-blow process
a) Delivery; b) Settle blow; c) Counter blow; d) Transfer from blank mold to blow mold; e) Reheat; f) Final blow with internal cooling; g) Takeout

The Corning ribbon machine is the classical example of mechanized glass-forming processes (Fig. 39). The machine is used to manufacture simple seamless products, such as light bulbs (1200/min), flash-bulb envelopes (2000/min), and Christmas tree ornaments. A *puff-and-blow* method is used in which a glass ribbon 50 mm thick is formed at about 1080 °C by two rollers. The lower roller has small indentations, which form small circular thicker regions in the glass ribbon. Transport of the ribbon brings the thickened regions above a hole. The glass sinks into the hole and is blown out by blow-heads that move synchronously with the ribbon. The turret chain machine is used for larger articles. This device also uses the puff-and-blow method but with individual glass gobs rather than a ribbon, thereby reducing the amount of cullet.

So-called gobs are delivered by the feeders of the glass furnace by shears cutting portions of a certain weight from a flow of glass melt. These gobs are conducted to the blowing machines.

Blowing machines for bottles in use today include the Lynch-10, capable of delivering 25 – 80 pieces per minute with bottle weights of 30 – 600 g; the Roirant-R-7, delivering 20 – 80 pieces per minute at weights of 100 – 1200 g; and the Hartford-IS-12, now manufactured by Emhart and Maul and used almost universally, which operates with the blow-and-blow process and produces about 10 pieces per minute. There are IS-6, IS-8, IS-10, IS-12 forming machines supplied by several machine manufactures; the number stands for the number of sections in series per machine. In each section 1, 2, or 3 gobs are simultaneously formed into a jar or bottle. A IS-8 machine with 3 gobs per section may produce more than 250 bottles per minute with a weight of about 200 g per bottle. Today, even larger machines are used for mass production.

6.1.2. Pressing

The role of air in blowing glass is taken over by a plunger (male half of the mold) in *pressing glass*. Blowing is used in the manufacture of deep items, whereas pressing is used particularly for relatively flat items such as dinnerware, optical and sealed-beam lenses, filter glass, or television tube panels. The press mold consists of three parts: the mold bottom, the plunger, and the ring; the latter functions as a seal between the other two parts. In hand pressing, molten glass is gathered on a solid steel rod *punty* (pontil) and drips into the mold bottom. A pair of shears severs the glass remaining on the punty from that in the mold. The plunger is then forced into the mold, causing the glass to flow into the space between plunger and mold. Movement of the plunger ceases when the space is filled. The plunger is withdrawn and the pressed glass removed from the mold. Three types of molds used for pressing are shown in Figure 40.

The principles of *machine pressing* are similar to those of hand pressing. For instance, a set of molds, commonly made of cast iron, bronze steel, or superalloys with galvanized surfaces,

Figure 39. The Corning ribbon machine

is mounted on a circular, horizontally rotating press table. Typically 8 – 16 mold positions lie on the periphery of this table. Glass flows from the refining end or feeder into a refractory bowl with a circular hole (spout) in the bottom. A reciprocating plunger of refractory material above this hole causes the glass to be extruded in pulses. Extruded glass is separated into gobs of the proper volume by a pair of shears directly below the hole. The motions of reciprocating plunger, shears, and press table are synchronized, ensuring that the gobs fall into successive molds. The plunger of the pressing process descends and presses the gob into the desired shape. The glass is usually cooled by blowing air against it. The hollow plungers are cooled separately by circulating coolant.

Mold temperatures must be monitored; glass may adhere to a mold that is too hot or have a wrinkled surface if the mold is too cold. A rubbering compound like a graphite suspension is applied to the mold, plunger, and ring to prevent adhesion of glass to the mold.

The pressing speed is determined by thermal conductivity, temperature, and temperature distribution. Normal pressing temperature is 670 – 800 °C; the lower limit is determined by the shapeability of the glass; the upper, by the oxidation resistance of the mold.

6.1.3. Blowing Combined with Pressing

In blowing and pressing, the gob is first pressed in a blank mold followed by transfer of the blank or parison to the blow mold. The blank is blown to its final shape in this second mold by a blow-head set over the neck (Fig. 41). For modern mass production IS machines with 10 – 16 sections are used to make press-blow items with wide necks (jars) and narrow necks (narrow neck press blowing) at high production rates. In each section two or three jars or bottles are produced. Generally, press-and-blow forming processes give a more uniform and more controllable glass distribution during forming than blow-and-blow processes. For bottles and jars press-and-blow processes allow smaller weights per item, while still obtaining sufficient mechanical strengths.

6.1.4. Drawing

The three forming processes used to manufacture glass tubing or rods are the Danner, Vello, and Schuller process. The Vello process has gained favor over the Danner process because of greater flexibility.

In the *Vello process*, molten glass flows downward through the annular space between a hollow vertical mandrel and a refractory or (noble) metal ring set in the bottom of a special forehearth, the bowl. Air blown through the mandrel into the fresh glass tube maintains the dimensions of both bore and diameter. The soft tubing, hanging in the shape of a catenary between the end of the mandrel and the drawing machine, is pulled onto a horizontal conveyor to the cutting machine.

Diameter tolerance for drawn glass tubing is typically 5 – 7 % for 6-mm tubing and 2 – 3 % for 150-mm tubing. Wall thickness tolerance is 11 – 15 % for the smaller diameter tubing and 12 % for tubing of 100-, 125-, and 150-mm diameter.

Figure 40. Types of molds used for pressing

Figure 41. Blowing combined with pressing
a) Delivery; b) Start of plunger pressing stroke; c) Full pressing stroke; d) Transfer from blank mold to blow mold; e) Reheat; f) Final blow with internal cooling; g) Takeout

The Vello process can accommodate a wide range of glass compositions and production rates of >45 kg/min with good dimensional control for tube diameters up to 65 mm. With special care, as required for thermometer tubing, the standard deviation of the tubing diameter can be held to 0.3 – 0.5 % of the nominal dimension.

The change in direction of the drawn tube from vertical to horizontal in the Vello process causes kinking in larger diameter tubes. A modification of the Vello process, the *down-draw process* prevents this by drawing tubing up to 280 mm straight down from the bowl with good dimensional control, while maintaining the production rates and glass-composition flexibility of the Vello process.

Rods can be drawn by any of the tube-drawing processes by turning off the air flow through the mandrel. The glass tube collapses, and rods are then formed, rather than tubing. The first mechanical drawing process for tubing glass was developed by Danner (USA) in 1917 (Fig. 42). In this process the liquid glass flows through a feeder opening on top of a downward-sloping rotating (5 – 10 rpm) mandrel (blowpipe). The glass distributes itself along the cylindrical surface of the mandrel and is drawn out into a tube. The mandrel consists of a hollow ceramic cylinder through which air is blown. This air flows through the resulting glass tube, which is released from the mandrel. Depending on the desired diameter of the glass tubes (1 – 70 mm), mandrels are used with a diameter varying from 100 to 700 mm.

The tube dimensions can be adjusted by means of the pressure of the compressed air and the drawing speed. At constant drawing speed, a higher compressed air pressure leads to a larger

tube diameter with a thinner wall thickness; a larger drawing speed with constant compressed air pressure results in a smaller tube diameter and a thinner tube wall. By combining these control factors, tubes of different dimensions can be manufactured with the same mandrel.

Figure 42. The Danner process

The consistency of the desired dimensions strongly depends on a constant discharge of the glass melt from the feeder and on a stable temperature profile of the glass during both the discharge of the melt from the feeder into the mandrel and drawing into a tube. The viscosity of the discharging glass melt from the feeder opening should be about 10^2 Pa · s and at the end of the mandrel the viscosity should be about $10^{3.5}$ Pa · s. The drawing speed amounts to about 400 m/min. for glass tubing of 2.5 mm diameter and about 100 m/min for 37 mm tube. The maximum production capacity of the Danner process is about 40 t/d.

In the Schuller process, developed in Germany in 1931, the glass tube is vertically drawn upwards. There are several modified versions of this process. The glass flows from the feeder into a rotating refractory dish with a blow pipe in the center at the bottom (cone). From this dish the glass tube is directly drawn upwards. Around the initial part of the glass tube a ceramic cylinder is located that rotates synchronously with the dish and which ensures a uniform temperature of the glass melt while it is drawn upwards. The tube dimensions are determined by the dimensions of the cone, the compressed air pressure, and the drawing speed. They can also be influenced by means of the cooling air, which is blown from holes in a cooling ring, located above the rotating cylinder. By using different blow pipes glass tubes can be manufactured with a diameter ranging from 3 to 50 mm. The production capacity per machine is up to about 3 t/d.

6.1.5. Redrawing

In the redrawing process, glass first is formed into the desired shape and subsequently reheated. The specific characteristic of this redrawing is that it preserves shape; e.g., a piece of glass with a square cross section of centimeter dimensions can be redrawn into a long rod with a square cross section with micron dimensions. The topology-preserving character of the redrawing process makes it ideally suited for miniaturization and is the basis for all optical waveguide technology.

6.1.6. Casting

Casting is a glass-forming process in which melt is poured into a mold. The most spectacular examples of cast products are telescope mirrors for the space observatories, often made from borosilicate glass; pieces larger than 5 m in diameter and weighing more than 36 t have been produced. Dimensional tolerances as low as 0.1 mm can be achieved in this process. Centrifugal casting is a variant of the casting process: a gob of glass drops into a mold, which then spins rapidly, spreading the glass by centrifugal force over the inside of the mold (Fig. 43). Funnel-shaped items, such as television tubes and missile radomes (nose cones), are formed by this process.

Figure 43. Centrifugal casting of television tubes
a) Mold glass; b) Distributor; c) Ejector valve; d) Grooving disk

6.1.7. Fritting

Fritting involves quenching a melt to create a highly thermally stressed glass that can be crushed easily in a ball mill. The glass is quenched between water-cooled rollers or poured into water. The former method is advantageous because it produces a thin friable ribbon that often gives more uniform mill feed.

6.1.8. Flat Glass Forming

6.1.8.1. Pilkington Float Process

Flat glass manufacture was revolutionized in the late 1950s by the invention of the Pilkington float process. This process has made other flat glass manufacturing processes (e.g., the Libbey – Owens, Fourcault, and Pittsburgh processes) obsolete. In the older processes, the glass sheet is pulled vertically through a slotted draw bar by the action of a pair of rolls contacting the glass melt sheet (Fourcault), or the glass is pulled over a bar. In the Pittsburgh system the glass is pulled upwards between pairs of rotating rolls after passing across a solid drawing bar. At the same time, the glass sheet is cooled by the draught created within the machine, which is about 13 m high. The maximum capacity of these machines is 50 t/d. Up to ten machines per furnace have been realized, resulting in a furnace capacity of about 300 t/d. This process still is being used in Eastern European countries and in the developing countries because of the relatively low investment costs.

In a similar system, developed by Libbey – Owens, the glass is also pulled vertically from the furnace. However the glass ribbon is bent across a bending roll at a height of about 1 m from the surface roof and subsequently pulled over a horizontal roller conveyor through a cooling zone. This process and the Fourcault process are still being used for thin glass (≤ 0.4 mm), for optical applications, and for LCD-displays.

In float glass production large cross-fired furnaces with regenerators are used for glass melting. Today, all-oxygen-fired furnaces are also used to melt the glass. The glass tank in which the molten glass is melted and conditioned prior to forming is typically 9 m wide, at least 45 m long, and usually contains more than 1200 t of glass (Fig. 44). Molten glass flows from the melting tank into a bath of molten tin, 3 – 4 m wide, 50 m long, and about 6 cm deep. The temperature of the molten tin bath (650 to 1100 °C) lies in the range of the working temperature of the glass. The glass surface flows and smooths itself while on the float bath, taking on the excellent surface quality of molten tin and thus requiring no further polishing. The glass body is rigid enough to be handled without damage by the time it leaves the bath at about 600 °C. Tin is used as flotation medium because of its surface tension (about 0.55 N/m), density (5.9 g/cm^3 compared with 2.2 – 2.5 g/cm^3 for glass), low melting point (232 °C), and relatively low vapor pressure. The thickness of the float glass ribbon is controlled by the pull rate and top rollers, which force the ribbon of still-molten glass to pile up or to spread. Sometimes an inorganic coating on the surface of the glass is directly applied just before the ribbon exits the tin bath section.

Figure 44. The Pilkington float glass process
a) Furnace; b) Molten tin; c) Float bath; d) Controlled nitrogen – hydrogen atmosphere to prevent oxidation of the tin; e) Lehr; f) Rollers

The advantage of Pilkington float glass, apart from the mirror quality of the glass surface, is the high production capacity relative to other drawing processes. The velocity of the emerging glass is about five to ten times higher than in the Libbey – Owens process. An additional economical advantage is that a float glass plant with a daily production of 400 – 800 t/d can be operated by four to six persons during an 8-h shift.

6.1.8.2. Rolling

Sheet glass with figured or embossed surfaces is formed by squeezing a stream of molten glass between rollers that have the embossing pattern on their surface. Wired glass is produced either by rolling a sheet of glass, covering it with wire, covering the wire with another sheet of glass,

and fusing both sheets together with the wire between them, or by making a sandwich of two sheets of glass with the wire between them which is then rolled.

6.1.8.3. Overflow Process

The overflow process is used by Corning Glass Works for specialty glasses such as ophthalmic glass, borosilicate glass, and glass that has to be chemically strengthened. The melt flows over two opposite sides of a trough, forming a combined sheet underneath the trough. The glass surfaces are untouched by a forming or handling tool until rigid, producing a surface quality comparable with that of glass manufactured by the float process.

6.1.8.4. Lamination

A stressed laminated glass with all surfaces in compression can be formed by laminating a low-expansion glass as a skin to a high-expansion glass core. The two glasses are fed into a laminating orifice, through which the composite sheet is drawn. This process is used primarily to produce food-service ware.

6.1.9. Fiberglass Forming

Four processes exist for manufacturing glass fibers: 1) rotary fiberizing, 2) steam or air blowing, 3) mechanical traction or drawing, and 4) flame blowing. The mechanical and rotary methods are the most important.

In *rotary fiberizing* a stream of molten glass is poured into a superalloy spinner rotating at 2000 – 3000 rpm. Centrifugal forces push the melt up the sides of the spinner and out through the perforated band around the periphery. A downward blast of air or hot gas stretches the loose fibers to a diameter of 3 – 6 µm. A phenolic binder in aqueous solution is used to bond the fibers together, and the fibers are collected as a mat on a conveyor belt and then cured in an oven and cut. A typical rotary fiberization operation is shown in Figure 45.

Figure 45. Rotary fiberization
a) Melting tank; b) Centrifuge with blowers; c) Binder spray; d) Uncured wool; e) Binder curing oven; f) Chopper; g) Products

Figure 46. Continuous drawing of textile glass fiber
a) Forehearth; b) Glass; c) Bushing; d) Size application; e) Strand formation; f) Traversing; g) Winding

The tanks used in *mechanical drawing* of continuous fibers contain up to 200 t of molten glass. Glass furnaces with up to 100 t fiberglass production per day exist. The molten glass flows from the forehearths into platinum alloy bushings (Fig. 46). The bushing, provided with several hundred nozzles, is located below a slot in the bottom of a canal (forehearth) on top of the

spinning section where the single filaments are spun into a single fiber (strand) by the collet. A solution is sprayed on the filaments to establish a fixation of the filaments in the strand and to give good adhesion properties. At the lower end, a rotating drum (collet) is located, which takes care of pulling and winding of the bundle of glass filaments (strand) at a constant velocity. Due to a meticulous system of traversing the strand upon the cylinder shaped package, it is possible to unwind the strand without any damage during subsequent treatment. Strand-winding velocities vary from about 1000 to 5000 m/min. Each bushing can deliver from several hundred up to more than 1000 glass filaments to be processed as fiber strand. Diameter control and winding techniques are similar to those encountered in optical waveguide manufacture.

6.2. Annealing

Annealing of a glass product is generally necessary after any forming operation. The glass is heated uniformly to a temperature sufficiently high to relieve any internal stress without causing excessive deformation of the object under its own weight. The ware is subsequently cooled slowly to prevent formation of new stresses. Cooling may proceed as rapidly as desired once the glass is rigid, provided that temporary stress does not cause breakage. Glassware is normally annealed in long, continuous ovens called *lehrs*, which are usually heated electrically, but also gas fired lehrs are applied. They are designed with great care to ensure a uniform side-to-side temperature, especially in the hottest zone. Bottles produced at a rate of 100 t/d are annealed in 15 – 20 min. Lehr design improvements include shortening and widening of the temperature chamber and new control techniques to ensure precise temperature distribution.

6.3. Secondary or Finishing Operations

6.3.1. Cutting

After emerging from the lehr, flat glass is rough-cut by scoring with a cutting wheel or a diamond. After inspection, the glass is cut into standard market sizes. Tubing is also rough-cut after leaving the conveyor, inspected for proper dimensional tolerance, and then cut to the required length. Several methods are used for this final cutting, ranging from scoring the tube and applying mechanical stress, to local heating of the tube with an electric wire and sudden chilling (thermal shock).

After glass blowing, part of the glass often has to be cut off mechanically by scoring the surface and applying a stress. Then this blown ware commonly contains broken edges. But the moil, or waste glass, is also frequently separated from blown ware by directing pinpoint flames onto the glass at the cutting line and simultaneously rotating the ware until separation of the moil and ware edges is complete. The surface tension of the fused glass produces a smooth, well-rounded edge. This operation is called burn-off or flame cutoff. Hot glass is normally trimmed by cutting the form with a hollow plunger.

6.3.2. Grinding

The purpose of grinding is to remove the upper layer of the glass surface. An abrasive produces a small check or crack in the glass, the dimensions of the checks depending on the grain size of the abrasive: increasingly finer abrasive produces a relatively smooth surface. Natural abrasive grits (e.g., quartz, sandstone, corundum, garnet, and diamond) are used, as well as synthetic grits (e.g., silicon carbide, aluminum oxide, and B_2O_3). Water or a suitable cutting fluid is used to speed up the process and to prevent overheating of the glass and glazing of the abrasive surface in bonded grinding wheels. Continued grinding results in an interconnected network of checks on the surface that break off with the formation of new pressure points. The result of grinding is an irregularly broken surface on the glass. By decreasing the coarseness of the grits in steps, the glass surface becomes more and more polished. In using very fine polishing techniques, the irregularities merge to a smooth surface.

A variety of grinding machines are used for different purposes. Grinding mills are large horizontally revolving iron plates, fed with loose abrasive grains such as silicon carbide and water. Copper engraving wheels used to engrave

art glass also employ loose abrasive grains and water. The common feature of bonded grinding wheels, belt grinders, and diamond-impregnated wheels is that the abrasive is embedded in the moving part. Another method is sandblasting, used to produce a diffuse surface.

6.3.3. Polishing

Polishing is carried out either mechanically or chemically. *Mechanical polishing* requires finely powdered abrasives such as rouge (ferric oxide) or CeO_2. These abrasives operate on the same principle as those in grinding. The abrasive is applied on a revolving buff made of felt, leather, lead, copper, or pitch. Polishing removes virtually no glass from the surface. The effect is thought to arise from induced surface flow at the molecular level, which fills local pits and removes the material lying above the average surface level. An optical polish produces very fine and accurate surfaces and is an art mastered only by specialists.

Chemical polishing includes acid polishing and flame polishing. In acid polishing the glass is submerged in a mixture of hydrofluoric and concentrated sulfuric acids. The material lying above the average surface level is preferably dissolved. In flame polishing a flame is directed onto a glass surface, producing a fire polish or fire glaze. In plasma polishing, short-term, local high temperature (plasma temperature: 8000 – 10000 °C) is used to melt the glass surface.

6.3.4. Heat Processing

In some finishing operations, reheating of glass is required. These operations include fusion sealing, shrinking, and tempering.

Fusion sealing is used when glass parts must be sealed together, e.g., the spun cast television tube (funnel) and its faceplate (panel). Fusion sealing is often carried out electrically. The two ends to be mated, are positioned in a lathe and heated by gas burners until the glass becomes sufficiently electrically conducting. At this stage an electric arc is struck to the glass, raising the edges of the glass pieces to the fusion temperature. The arc continues for a few seconds after the parts are joined. The seal is worked by blowing and pulling after the arc is turned off. Often, a low melting sealing glass is used to seal two glass parts together.

Electrostatic sealing (anodic bonding) is a type of field-assisted glass-to-metal sealing, which has been used successfully on steels, alloys, and silicon substrates. The application of a large d.c. field to a closely-fitted glass-metal interface allows sealing at temperatures well below those required for viscous flow, wetting, and chemical bonding. Both strong electrostatic forces and ionic diffusion have been implicated in the mechanism.

Shrinking is used to produce tubing with an extremely close inside diameter tolerance, e.g., for fluid flowmeters. A mandrel is inserted into the tubing, and the assembly is heated until the glass softens. The tubing collapses onto the mandrel after the space between the two parts is evacuated. Tubing of any shape (e.g., square, rectangular, triangular) can be produced in this manner. Optical glass fibers are produced from massive cylindrical rods by heating until the glass softens and subsequently stretching the rod to the desired fiber diameter.

Thermal tempering, or quench strengthening, is used to strengthen glass by stressing to bring all surfaces into compression. This finishing operation is used for flat glass, piping, some cookware (e.g., pots and pans), tumblers, gauge and sight glass. The ware is heated close to the softening point at least above the strain point and then quenched by a blast of air, a fused salt bath, or some other means. The outer skin of the ware solidifies whereas the inner mass remains soft, resulting in compression of the outer skin on further cooling. An increase in strength by a factor of four or more can be obtained in this manner, although in practice most thermal tempering treatments result in a strength increase by a factor of 2 – 3. Glass thinner than about 0.5 mm, and glasses with very low thermal expansion coefficients such as fused silica, and 96 % silica cannot be tempered.

6.3.5. Sintering

Sintering is used whenever intricate shapes such as porous filters and tiny sealing beads are required. A variety of glass compositions from lead glass to fused silica can be used. The glass

is finely ground, made into a paste or slurry with a liquid, and cast or pressed to the green, intermediate shape desired. After drying, the green form is heated until the particles soften and fuse with concomitant shrinking of the ware. Sintering usually produces a translucent glass. which can, however, be rendered transparent with a density similar to that of the original glass.

6.3.6. Chemical Treatment

Hydrofluoric acid is used for *etching* (e.g., graduations on volumetric laboratory glass ware). The item is covered with acid-resistant wax in which the graduations are cut, and the exposed glass is then etched by immersion in a hydrofluoric acid bath. Light bulbs are frosted with hydrofluoric acid or by injection of ammonium fluoride solution into the bulb.

Staining involves ion exchange between alkali metal atoms in the glass and copper or silver in the stain, producing a red or amber color, respectively. Red stain is used for markings on volumetric glassware, and silver stain for ware with low near-UV transmittance.

Figure 47. Na^+/K^+ exchange of flat glass in a KNO_3 melt at 440 °C; the compressive stress at the surface reaches a value of 430 – 480 MN/m^2 after a short time.

Strengthening also involves ion exchange: the glass is immersed in a hot salt bath, which causes small alkali metal ions near the surface of the ware to be replaced by the larger ions from the bath. The surface is under compression because of the presence of the larger ions. The degree of compression can be as high as 700 MPa, depending on the glass composition and the strengthening cycle employed. The compressive layer can be much thinner (100 μm) than that obtained by tempering. Examples include windows of supersonic aircraft, glazing, and ophthalmic lenses. Figure 47 shows the compressive stress in the surface layers of a glass treated in a potassium nitrate melt as a function of the duration of the treatment.

6.3.7. Surface Coating

Vitreous enamels are applied by spraying, silk screening, and decalomania, i.e., the transfer of pictures from one medium to another. They are fused to the ware at high temperature but below the softening point of the glass itself.

Metal oxide coatings are produced either by applying a liquid suspension of metal oxide to the surface and then firing it or by vapor deposition of metal oxides on the glass. These coatings are used on flat glass as a means of controlling transmission and reflection of light, as electrical semiconductors in tin oxide films, as resistors in electronic circuitry, as defrosting agents and on aircraft glazing. Metal oxide coatings (hot end coatings) are also applied on container glass articles to improve scratch resistance and adhesion to polymer coatings (cold end coatings).

Metallic coatings are produced by special coating installations that sputter metal layers onto glass surfaces at low pressures. They are used for thermal insulation of flat glass products. The coating material is bombarded with argon (positive) ions generated in a corona discharge at a high positive voltage and accelerated in an electric field. Since the deposition source is located at the cathode, the process is also called cathode atomization. The atoms or molecules released from the target by the impingement of the argon ions are deposited on the substrate. During the sputtering process, other interactions occur between the argon plasma particles, the target, and the substrate, which can influence the quality of the coating. The uniformity of the coatings is generally good; the growth rate is typically 0.5 – 3 nm/s for d.c. sputtering. However, this rate is too low for bulk production. The growth velocity can be increased by a factor of ten or more by using the magnetron (microwave) sputtering technique, in which the intensity of the argon plasma is increased by focusing with a magnetic field.

Apart from metals (Ag, Cu, Au, Ni, Cr, Ti, etc.) also oxides, nitrides, and carbides can be applied with the sputtering or PVD method. This is realized by bringing reactive gas mixtures (e.g., Ar/O_2) into the reaction chamber (reactive deposition/sputtering).

In physical vapor deposition (PVD) processes the glass substrate need not be heated. However, a chemical bond is then generally not formed between the coating and the glass substrate; there is only a weak physical adhesion. Therefore PVD coatings on glass also are called soft coatings. Spray or CVD coatings or mostly hard coatings. PVD methods are used on a large scale for the application of sunlight protection and heat reflecting (low E) coatings on window glass. Sun-protecting coatings partially transmit the visible part of the spectrum (0.4 – 0.8 μm) and reflect solar IR radiation (0.8 – 2.5 μm).

Heat-reflecting coatings must be transparent throughout the whole solar spectrum (0.4 – 2.5 μm) to obtain the heat from the solar radiation, and reflective beyond 2.5 μm, where the spectral range of the thermal radiation at room temperature begins. In this way the heat in the room is not lost by thermal radiation through the windows.

Lacquers are used for decorative purposes, for example, in Christmas ornaments and electric light bulbs.

Tin oxide and titanium oxide coatings are applied to container glass by spraying or by atmospheric CVD. In the latter case, the hot bottles pass through a reaction tunnel with an oxidizing atmosphere, in which the coating material (e.g., $SnCl_4$) is present as a vapor. In this case, deposition of SnO_2 will take place.

The CVD process is also used industrially in combination with the float-glass process. In the reducing atmosphere of the tin bath section, Si layers are formed on the glass surface by treatment with silane (SiH_4). The Si coatings have a thickness of about 30 nm and function as sun protection mainly by reflection for wavelengths up to 1 μm. They do not reflect heat because of the decreasing reflection of the Si layer at higher wavelengths ($\gg$ 1 μm).

In oxidizing atmospheres SnO_2 layers on the glass surface (Pilkington) can be formed from $SnCl_4$.

7. Uses

7.1. Silica and Silica-like Glass

Pure vitreous silica is the only industrially important single-component glass. The important characteristics of this material are its extremely low coefficient of thermal expansion, high operation temperature, good chemical durability, and excellent UV transparency (Section 2.2.1). The principal drawback is the high production cost resulting from the high melting temperature (>2300 K) required to obtain transparent material, which limits the number of economical applications. Nevertheless, several important uses exist. A more detailed discussion of applications of silica is given in [131].

Chemical purity, good chemical durability, and thermal shock resistance make vitreous silica the glass of choice in chemical laboratories. Thermal shock resistance is important when making sleeves around high-temperature thermocouples. Transparency to far UV radiation and low thermal expansion are the most important properties in optical applications: e.g., lenses, incandescent tungsten halogen cycle lamps, solar cell covers, high optical quality vitreous silica (Corning Code 1940), windows for space vehicles, and mirror blanks. Another important application is thin-film dielectric coating in integrated circuits. The refractory nature of silica (SiO vapor pressure <0.87 Pa in vacuum, and 3.9 mPa at 20.3 kPa partial oxygen pressure and 2000 K) and its inertness make it the laboratory ware of choice in the semiconductor industry.

Less critical components are made of silica-like material (Vycor), produced at ca. 1800 K; the process consists of melting 65 – 86 wt % SiO_2, 10 – 30 wt % B_2O_3, and 4 – 5 wt % Na_2O. Glasses with these compositions exhibit phase separation into a silica-rich and a sodium borate-rich phase at ca. 870 K. The latter is leached out in the presence of hot acid, resulting in a porous "thirsty" glass with about 96 wt % SiO_2 and 3 wt % B_2O_3. Heat treatment of this silica-rich skeleton results in a dense, fully transparent glass, used as laboratory ware.

Porous glasses have been made by (1) the viscous sintering of powdered glass, with or without soluble fillers, or (2) by heating and leaching certain phase-separable borosilicate

compositions. The latter method gives materials with controlled, uniform pore diameters of 4 – 300 nm. Applications include micro- and ultrafiltration, chromatography packing, desiccants, and substrates for immobilization of enzymes used in biotechnology. A typical 96 % SiO_2 Vycor-type porous glass has 4 nm diameter pores, a pore volume of 28 %, and a specific surface area of 250 m^2/g.

Specialty glasses, with thermal expansion even lower than that of fused silica, have been developed for use as astronomical mirror blanks. In addition to silica glass, they contain TiO_2, ZrO_2, and B_2O_3 or Al_2O_3. Inclusion of titania and zirconia (ZrO_2) results in a continuous decrease in the coefficient of thermal expansion.

7.2. Flat Glass

7.2.1. Reflective Glass

Reflective glass is covered with a metal or metallic oxide coating on one surface, furnishing high reflectivity in the desired wavelength range. A coating that provides maximum infrared reflectance reduces heat losses through windows. The coatings are produced by wet chemical, vacuum, or pyrolytic deposition. In *wet chemical deposition* the metal is precipitated from solution onto the surface of the glass. These coatings are fragile and must be protected after application. *Vacuum deposition* involves evaporation of the metal by electric heating in a vacuum chamber. Such coatings are not as fragile as chemically deposited coatings, but the glass cannot be tempered or heat strengthened after coating. *Pyrolytic deposition* involves spraying a solution containing the desired metal oxide onto the glass, which is held near red heat. The oxide is integrated into the surface and is extremely durable. Glass coated in this manner can be tempered and may be exposed to weather without a protective coating.

7.2.2. Laminated Glass

Laminated glass is a sandwich consisting of a plastic layer, usually a poly(vinyl butyral), between two or more glass sheets. Automobile windshields are made of laminated glass designed to be thin enough to flex slightly, thereby reducing the risk of injury in the event of collision. The plastic inner layer may be tinted to act as an IR filter. Laminated glass is more resistant to fracture than monolithic glass, and in the event of fracture, the plastic layer holds the glass fragments in place and absorbs part of the impact energy. Three-layer laminated glass is used for material requiring high impact resistance.

7.2.3. Solar Glass

Solar glass is low iron oxide soda lime glass. The IR transmittance of such glass may be as high as 93 %. This glass is used in solar collectors for heating water and in passive solar-heating systems for buildings.

7.3. Laboratory Glassware

Many laboratory items (e.g., beakers, Petri dishes, reaction flasks, volumetric equipment, ground joints, stopcocks, fritted ware, test tubes, and thermometers) are made from glass. The particular composition and thermal expansion of these glasses are given in Table 29. The corresponding properties of soda lime glass are included for comparison.

Borosilicate glass has the lowest coefficient of thermal expansion of all glass produced in bulk. Its resistance to thermal failure is high, and therefore, borosilicate objects can be heated and cooled more rapidly than high-expansion glasses. Aluminoborosilicate glass also has a high chemical durability with an appreciably larger expansion coefficient. Fused silica and 96 % silica glassware can be used at still higher temperature and will, of all the glasses mentioned here, best withstand severe change in temperature. Beakers of 96 % silica can be heated to redness and dropped into ice water without breaking. The four glasses listed above have few chemical constituents, have a low alkali-metal content, and are free from heavy-metal oxides, a distinct advantage in chemical analysis.

Table 29. Characteristic thermal properties of laboratory glassware

Glass type	Thermal coefficient expansion, 10^7 K^{-1}	Maximum operating temperature, °C	
		Continued use	Short-term use
Borosilicate, low expansion	32.5	510	
Aluminoborosilicate	55	520	
Soda lime	80 – 90	500	
96 % Silica	8	900	1200
Fused silica	5.5	1000	1350 – 1450

7.4. Light-Sensitive Glass

7.4.1. Photosensitive Glass

The sensitivity of some chemicals to light has been known since the time of DAGUERRE (1839). Characteristics of such chemicals have been reviewed [132]. An important process for glass applications involves cleavage of a molecule of silver halide under the influence of light, resulting in its reduction to metallic silver. Photolysis is used to produce photosensitive glass, the process consists principally of irreversible photoinduced homogeneous nucleation.

Photosensitive glasses contain a small amount of silver. Ultraviolet light or X-rays are of sufficiently high energy to reduce the silver ion and mobilize the homogeneously dispersed silver atoms, causing the silver to cluster in small particles. In Fotoform, lithium silicate is added to photosensitive glass. Subsequent heat treatment of Fotoform results in an opal glass due to the growth of lithium meta- or disilicate crystals that use the silver nuclei as substrates. Masking the glass before exposure produces, after heat treatment, a pattern which duplicates that of the mask. The exposed glass area dissolves, because of the presence of lithium silicate, approximately 14 times faster than the unexposed area; patterns can, therefore, be etched out, leaving void areas where the glass was exposed to radiation.

The principal use of photosensitive glasses lies in the manufacture of intricate and precise patterns. For example, as many as 250 000 holes, each 0.23 mm in diameter, have been etched on an area of 654 mm^2.

7.4.2. Photochromic Glass

Photochromism is the change in color of a solid upon irradiation with light of certain wavelength. This process can be reversible or irreversible. Most common practical applications use reversible photochromic materials [133]. The effect is based on the photolysis of a silver halide. In contrast to photosensitive glasses, however, after rupture of the halogen – silver bond, the halide ion is not sufficiently mobile to move away from the silver atom and the bond is reestablished during darkness. Thus the system is excited by light and, in darkness, reverts to its ground state.

The principal application of this effect is in photochromic lenses, with or without a corrective prescription. Corning photochromic filter (CPF) lenses have specially formulated compositions. These lenses are fired in hydrogen, turn yellow or red, maintain their photochromic character, and cut out blue light. They are made for people with diseases of the cornea or retina.

7.5. Display Devices

A cathode-ray tube (CRT) consists of three parts: a glass envelope or bulb, a phosphor screen, and an electron gun. The bulb also consists of three parts: the panel on which the phosphor screen is deposited, the funnel, and the neck in which the electron gun is sealed. These three parts are produced separately, and two of them are subsequently flame sealed with a solder glass (frit). The panel is usually pressed, the funnel is either pressed or centrifugally cast, and the neck is made from glass tubing.

Cathode-ray tubes have a number of built-in safety features. To prevent implosion, bulbs are designed to withstand an external pressure

of at least 3 atm (303 kPa); in addition, a tension band may be placed around the periphery of the panel skirt. To prevent exposure of the viewer to X-rays, the glass composition and wall thickness of the bulb are adjusted to maximize the 20.6-kV linear X-ray absorption coefficient of the glass; for Asahi – Corning color TV glass, this is currently 28.5 cm^{-1} for panels and 64.8 cm^{-1} for funnels (see also → Display Technology, Chap. 4.).

7.6. Glass Fibers

The basic products of the glass-fiber industry are unbonded and bonded wool, mats, staple fiber, cut strands, textile strands, sliver (i.e., parallel, overlapping, and untwisted bundles of noncontinuous or short-length fibers), and molded products such as pipe insulation or ceiling tile (see also → Fibers, 5. Synthetic Inorganic, Chap. 2.).

Glass-fiber wool insulation can reduce heat loss to one-half to one-fifth. Typical overall coefficients of heat transmission, or *U* values, for three wall structures are collected in Table 30.

Table 30. Typical *U* factors (heat conductivity) for wall structures

Type of construction	*U*, $W\,m^{-2}\,K^{-1}$	
	Uninsulated	Insulated
Wood frame	0.6 – 2.4	0.23 – 0.35 ∗
Masonry	1 – 4	0.4 – 0.4 ∗∗
Concrete block	1 – 3	0.32 – 0.45 ∗∗

∗ Based on 10-cm-thick insulation.
∗∗ Based on 7-cm-thick insulation.

7.7. Molded Optics

The impetus behind the fabrication of molded lenses is the production of cheap optical lenses for mass-produced cameras or optical memory disks. The challenge is to produce a bulk optic lens with a smooth surface and proper dimensions directly by molding only, bypassing the finishing stage. Four parameters are important in this process: (1) the materials from which the mold is made, (2) the variations in the mold, (3) the molding process itself, and (4) the size of the molded product. Glass compositions used in this process can vary over a wide range from fused silica to lead fluorophosphate. The Kodak company is most advanced in this technology, producing millions of aspheric lenses per year.

7.8. Glasses for Nonlinear Optical Devices

Glasses for nonlinear optical devices represent the frontier of research in glass chemistry and physics. The nonlinear effect in glass consists of a change in the refractive index of the glass as a function of the intensity of incident light. A necessary, but not sufficient, condition seems to be a high-index glass [134]. This nonlinear effect is small in standard glass but, sampled over a large volume as in optical waveguides, sufficiently large to function as a switching device. The aim is to increase photonic switching and signal processing by producing optical transistors that operate in the range of 10^{-12} s (ps) to 10^{-15} s (fs), compared with standard transistors, which operate in the range of 10^{-6} – 10^{-9} s (μs – ns).

8. Economic Aspects [143–147]

World production of glass is estimated at 80×10^6 t/a. The market shares (expressed in mass %) of major applications are shown in 48.

Figure 48. Market shares of major glass applications

The most important glass producing regions in the world are the EU with about 25.7×10^6 t of glass production in 1995 (turnover, including secondary glass manufacture, ca. $\$ 40 \times 10^9$); the United States with 13.5×10^6 t of glass in 1994; and Japan and Korea with about 8×10^6 t/a of glass. Glass production is growing in China, South America, and Turkey. The total turnover of primary glass products worldwide is estimated at about $\$ 130 \times 10^9$ annually.

In the United States the 1994 glass production value amounted to \$ 24×10^6.

The principal container glass producers are: Owens Brockway (USA), Consumer Glass (Canada), Ball-Foster (USA, owned by Saint Gobain), St. Gobain, Gerresheim (Germany), Heye Glas (Germany), BSN Emballage (France), PLM (Sweden), Yamamura Glas (Japan), Vetropack (Switzerland), Oberland Glas (Germany, owned by St. Gobain), Sise-Cam (Turkey), Nienburger Glass (Germany), ACI (Australia, owned by Owens Brockway), AVIR (Italy, owned by Owens Brockway).

Glass containers are used for food, beverages, liquor and wine, beer, perfume, pharmaceutical, and cosmetic products. The total container glass production in 12 countries (Belgium, Germany, France, Italy, The Netherlands, Ireland, Portugal, Spain, Denmark, Greece, Luxemburg, UK) of the European Union in 1994 was 16.4×10^6 t, in the United States about 13.5×10^6 t (1994); and in Japan 2.6×10^6 t (1990). Total annual world production is about $45-50 \times 10^6$ t container glass. An average 3.5 % production growth has been accomplished since 1986 in the EU container glass industry.

There are a very large number of domestic and tableware crystal glass producers worldwide, but the most important companies are: Durand-Verrerie Cristallerie d'Arques (France), Bormioli Rocco (Italy), Libbey Glass (USA), Waterford Crystal (Ireland), Kosta Boda (Sweden), Sise-Cam (Turkey), Nachtmann (Germany), Schott (Germany), Kedung (Indonesia), Crestalux (Argentina), Vitrocrisa (Mexico), Sasaki Glass (Japan), Anchor Hocking (USA). Annual production is estimated at 3.2×10^6 t/a. The US turnover for tableware glass products in 1996 was \$ 1.9 billion.

The major flat glass producers are: Pilkington (UK), Asahi (Japan), PPG Industries (USA), Glaverbel (Belgium), Saint Gobain (France), Ford (USA, since 1998: Visteon), Libbey Owens Ford (USA, owned by Pilkington), AFG (USA), Central Glass (Japan), Nippon Sheet Glass (Japan), Keumkang (South Korea), Hankuk (South Korea). The companies produce mainly float glass for automotive and architectural applications. China is an important producer of flat glass, with about 30 – 40 operating float furnaces. Float glass production in the United States in the mid-1990s was ca. 3.7×10^6 t/a. In the EU in 1995, 5.1×10^6 t of float glass was produced. Japanese float glass production in 1990 was about 2.7×10^6 t.

Mineral wool is produced by a few large companies and many small companies. The principal mineral wool producers worldwide are: Johns Manville (USA), Owens Corning Fiber Glass (USA), Certain Teed (USA, affiliated to Saint Gobain), Saint Gobain-Isover (France), Guardian Fiberglass (USA), Knauf Fiber Glass (USA), Rockwool (Denmark). The major markets for mineral wool are structural insulation, industrial equipment insulation, pipe insulation, and substitute for soils in agricultural applications.

Continuous fiberglass for textile or reinforcement applications is mainly produced by PPG FiberGlass (USA), Owens Corning Fiberglass (USA), Vetrotex (France, owned by St. Gobain), Johns Manville (USA), Hankuk Vetrotex (South Korea), Asahi Fiber Glass (Japan). The EU production of continuous fiberglass amounted to 462 000 t in 1995.

The advanced and specialty glass market includes optical waveguides for telecommunications, electronic devices such as thick-film dielectrics, resistors, thermistors, glasses for sealing ferrites in magnetic recording, electronic displays, glass nozzles for high speed printers, channel electron multipliers, high-performance composites such as alumina borosilicate glass for use in secondary structures in aircraft, medical or dental bioglasses (based on calcium phosphates), glass ceramics, and vitrified high-level nuclear waste.

Among the worldwide producers of specialty glasses and TV glasses are Schott (Germany), General Electric (USA), Corning (USA), Nippon Electronic Glass (Japan), Thomson (France), Philips Display Components (The Netherlands), Asahi (Japan), Samsung Corning (South Korea), and Hankuk Electric Glass (South Korea).

Glass for lighting applications, such as bulbs, tubes, and automotive lamps, are produced by Philips Lighting (The Netherlands), Osram Sylvania (Germany, USA), and General Electric (USA).

Sodium silicates, mainly intended for further chemical processing, are produced in Europe and United States by companies like Henkel (Germany), AKZO Philadelphia Quartz (The

Netherlands, USA), Rhône-Poulenc (France), and PPG (USA).

1. Introduction

The development of glass ceramics is a comparatively recent advance in materials science. The phenomenal growth in a wide variety of applications for these materials since their discovery by Stookey in the late 1950s attests to their great utility.

Glasses are formed when molten materials are cooled and form a solid without crystallization (→Glass). Glass ceramics, however, are uniformly grained, crystalline materials which are made by controlled nucleation and crystallization of homogeneous glasses. Crystallization is induced by a nucleating agent and heat treatment. The major advantage of glass ceramics over conventional ceramics is that fully densified bodies with complex shapes can be manufactured using standard hot glass forming techniques. Glass ceramics also offer a variety of unique, uniform physical properties, including great strength, machinability, transparency, and thermal shock resistance that cannot be attained in either glass or conventional ceramics.

Literature on glass ceramics is not as extensive as that for glasses. The excellent recent reviews of Beall and coworkers [1–4] and Smith [5] together with the books written by Vogel [6] and Strnad [7] and the one edited by Lewis [8] give a proper overview of glass ceramic technology.

2. Nucleation and Crystallization of Glass Ceramics

The specific properties of glass ceramics are controlled by the physical properties of the crystalline phases developed in the glass upon heat treatment and also by their microstructure, i.e., the textural relationship between the crystalline phases and the residual glass. The uniformity and reliability of these properties is a consequence of the uniform grain size of the crystalline phases. Therefore, an important prerequisite for the formation of glass ceramics is efficient nucleation of the crystalline phases. The heat treatment (ceramming) of glasses to produce a glass ceramic typically involves two or

10.1002/14356007.a12_433

more steps: a lower temperature step to induce nucleation (*the nucleation hold*), and one or more higher temperature treatments to promote crystal growth (*crystallization hold*).

2.1. Homogeneous Nucleation

Homogeneous nucleation occurs when crystals are formed within a supersaturated fluid without addition of foreign particles. The parameters involved in crystal nucleation are shown in Equation (1) which expresses the steady-state homogeneous nucleation rate in a one-component supercooled system [8], [9]:

$$I = A \exp\left[-\left(W + \Delta G_{\mathrm{D}}\right)/kT\right] \tag{1}$$

Here I is the number of nuclei formed per unit volume, W is the free energy barrier to formation of a nucleus of critical size, ΔG_{D} the kinetic barrier to nucleation, k is Boltzmann's constant, and T is absolute temperature. The preexponential factor A can be expressed to a first approximation by

$$A = n_{\mathrm{v}}\left(kT/h\right) \tag{2}$$

where n_{v} is the number of formula units of the nucleating phase per unit volume of liquid and h is Planck's constant.

The parameter ΔG_{D} is usually expressed as the activation energy of diffusion in the Arrhenius equation

$$D = D_0 \exp\left(-\Delta G_{\mathrm{D}}/kT\right) \tag{3}$$

where $D_0 = kT\lambda^2/h$, λ being the jump distance of the atoms in the direction of diffusion. Assuming validity of the Stokes–Einstein relation, D can be expressed in terms of the viscosity η as $D = kT/6\pi\lambda\eta$. Thus $\exp(-\Delta G_{\mathrm{D}}/kT) = h/6\pi\lambda^3\eta$, and Equation (1) becomes

$$I = \left(A_{\mathrm{c}}T/\eta\right) \exp\left(-W/kT\right) \tag{4}$$

where A_{c} is $n_{\mathrm{v}}k/6\pi\lambda^3$. The free energy barrier to formation of a critical spherical nucleus W is

$$W = 16\pi\sigma^3 V_{\mathrm{m}}^2/3\Delta G^2 \tag{5}$$

where σ is the interfacial energy per unit area between crystal and liquid, V_{m} the molar volume of the crystalline phase, and ΔG the change in free energy per mole of material crystallized. Substitution into Equation (4) gives the final expression for the steady-state homogeneous nucleation rate as

$$I = \left(A_{\mathrm{c}}T/\eta\right) \exp\left(-16\pi\sigma^3 V_{\mathrm{m}}^2/3\Delta G^2 kT\right) \tag{6}$$

in which time does not appear explicitly because I does not vary with time in steady-state homogeneous nucleation.

Although exact evaluation of Equation (6) is not possible due to the lack of relevant thermodynamic data, interfacial energy values, and n_{v} data, this equation is still a useful guide for making adjustments to produce an efficiently nucleated glass ceramic. For example, it indicates that lowering the interfacial energy σ should have the largest effect on increasing nucleation efficiency. This might be accomplished by slight variations in glass composition, in particular by addition of WO_3 and MoO_3, which effectively reduce surface tension.

Similarly the number of nuclei per unit volume I will be larger if the change in free energy between liquid and crystalline precipitate is large. Although this free energy change is largely beyond experimental control, introduction of components which preferentially enter into solid solution with the crystalline phase may lower its free energy relative to the liquid and hence increase the number of nuclei.

Inspection of Equation (6) also suggests that increasing viscosity will decrease the nucleation efficiency because of impeded transport of nutrients to the nucleus. Lowering the viscosity at the optimal nucleation temperature is therefore desirable, although this is limited because the article may sag during the nucleation hold.

The least understood parameter in Equation (6) is n_{v}, the number of formula units of the nucleating phase per unit volume. The reason for this is a general lack of understanding of the relationship between glass and crystalline structure. Intuition suggests that structural similarity between the glass and the crystalline structure would accelerate nucleation because of the increased probability of forming a critical nucleus, hence increasing n_{v}.

An expression for the time-dependent nucleation rate I' is given by Kaschiev [10]:

$$I' = I\left[1 + 2\Sigma\left(-1\right)^m \exp\left(-m^2 t/\tau\right)\right] \tag{7}$$

where the summation over the index m is from one to infinity, $\tau = 48\sigma\lambda^5\eta/\pi V^2 \Delta G_v^2$ is the induction time, I is the steady-state nucleation rate, and t is time.

Figure 1. A two-dimensional slice through three-dimensional Voronoi cells calculated for a random distribution of nucleation sites separated by an average distance of 32 µm (A, 40 points) and 16 µm (B, 400 points) Courtesy of Leslie Button (Corning Incorporated).

2.2. Heterogeneous Nucleation

Homogeneous nucleation occurs in only a small number of glass systems, such as $Li_2O \cdot 2\,SiO_2$, $Na_2O \cdot 2\,CaO \cdot 3\,SiO_2$, $BaO \cdot 2\,SiO_2$, and $SiO_2 \cdot P_2O_5$. No industrially important glass ceramic systems nucleate homogeneously. In most glass ceramic systems, nucleation is heterogeneous, i.e., it is a consequence of epitaxial growth of the dominant crystalline phase upon nuclei of a foreign or earlier formed phase. The latter are usually crystallites of relatively refractory and/or insoluble phases (e.g., rutile, anatase, ZrO_2, $ZrTiO_4$, Cr_2O_3, and many of the noble metals), but can also be globules of an immiscible glass. As a result, "nucleating agents" or "nucleants" such as TiO_2, ZrO_2, P_2O_5, Pt, Pd, and Au are essential components in the bulk composition of most commercial glass ceramics. The nucleation and growth of the nucleating agent itself can be considered to be homogeneous.

The equation describing the steady-state heterogeneous nucleation process is analogous to that describing homogeneous nucleation:

$$I^* = n_s\,(kT/\eta)\exp\left[-\left(W^* + \Delta G_D\right)/kT\right] \qquad (8)$$

In this equation $W*$ is a function of the contact angle between the nucleating agent (substrate) and the epitaxial phase, and n_s is the number of formula units per unit volume (i.e., number density) of the latter in contact with the substrate. The contact angle is assumed to be a function of the degree of lattice mismatch between substrate and epitaxial phase. The effectiveness of heterogeneous nucleation therefore depends on the structural relationship between the substrate and the epitaxial phase and on the number density of heterogeneous nuclei in the supercooled liquid. The lattice constants of the nucleating agent and the desired crystalline phase should agree to within ca. 15 %. Examples are given in Table 1.

The number density of heterogeneous nuclei depends strongly on solubility; effective nucleating agents have low solubilities at the nucleation temperature. For any crystalline phase, solubility is controlled by the interactions among the melt components. Using TiO_2 and ZrO_2 as examples, their relative efficacy as nucleating agents is partly governed by the relative stability of titanate versus zirconate melt complexes. In alkali silicate glasses TiO_2 is not an effective nucleating agent because it forms stable melt complexes with alkali-metal ions; ZrO_2, on the other hand, is more effective because complex formation is not favored to the same degree [11].

Table 1. Lattice constants of crystalline phases used in glass ceramics and their mismatch relative to rutile (TiO_2 nucleant)

Crystalline phase	Lattice constant, nm			Deviations from TiO_2*	
	a	*b*	*c*		
Rutile (TiO_2, nucleant)	0.46		0.30		
β-Spodumene ($LiAlSi_2O_6$)	0.95	0.83	0.52	*a*:	3.7 % ($2a_r$)
				b:	−9.4 % ($2a_r$)
				c:	−11.2 % ($2c_r$)
β-Eucryptite ($LiAlSiO_4$)	0.52		1.12	*a*:	12.6 % ($2a_r$)
				c:	−5.3 % ($4c_r$)
Cordierite [$Mg_2Al_3(AlSi_5O_{18}$]	1.70	0.98	0.93	*a*:	−6.7 % ($4a_r$)
				b:	6.8 % ($2a_r$)
				c:	1.9 % ($2a_r$)

* Deviations are expressed as percentages relative to the quantity defined in parentheses. The subscript r denotes rutile.

The effect of the number density of heterogeneous nuclei on the grain size and, hence, the texture of a glass ceramic is illustrated in Figure 1 with the aid of three-dimensional Voronoi cells. Voronoi cells are geometric constructions in which polyhedral elements are calculated between a set of points such that the distance to each point is halved. In Figure 1, two cross sections of three-dimensional Voronoi cells have been calculated, the one with small crystallites represented by 400 points, the other with large crystallites represented by 40 points. As illustrated in Figure 2, a small number of nucleation sites results in large crystallites (A), a large number in small crystallites (B).

2.3. Crystal Growth

Once the critical radius of a crystallite is exceeded, the free energy of the system is lowered by further crystal growth rather than by crystal dissolution (Fig. 3). In both homogeneously and heterogeneously nucleating systems, the critical radius can be defined as

$$r_c = -2\sigma V/\Delta G \tag{9}$$

where V is the volume of the critical nucleus and σ is the surface free energy. The effect of the nucleating agent on the critical radius in a heterogeneously nucleating system is expressed through the surface energy term; this will be smaller the greater the structural congruence between the nucleating agent and the crystalline phase. The rate of crystal growth ζ is governed by parameters similar to those involved in nucleation. An equation has been derived by Jackson [13] to describe continuous growth by random attachment of atoms to surface sites:

$$\zeta = \lambda\nu\,(H\Delta T/kT_m T) \cdot \exp(-Q_f/kT)\exp(-H/kT_m) \tag{10}$$

The rate of crystal growth depends on the thermodynamic driving force H (the enthalpy of fusion), the jump distance λ, the vibrational frequency ν, the atomic mobility as expressed by an activation energy for diffusion Q_f, and ΔT, the temperature difference between the melting temperature T_m and the growth temperature T. As with nucleation, the mobility term can be expressed in terms of diffusivity and viscosity by the Stokes – Einstein relation. Equation (10) then becomes

$$\zeta = h\nu/6\pi\lambda^2\eta\,(H\Delta T/kT_m T)\exp(-H/kT_m) \tag{11}$$

2.4. Heat Treatment

Although the parameters governing Equations (8) and (11) are similar, the functional dependence of the nucleation rate and the growth rate on these parameters is not. Consequently, nucleation and growth rates generally attain maxima in separate temperature regimes (Fig. 4). As a result, heat treatment (ceramming) of a glass article to form a glass ceramic typically includes at least two steps. The first of these is the *nucleation hold:* a soak or gradual heating at relatively low

temperature, usually about 50 – 100 °C above the annealing point of the glass. Following the nucleation hold, the temperature is raised rapidly to that of the crystallization step. The article is then heated at constant temperature until crystal growth is complete and the desired microstructure attained. This is termed the *crystallization hold.*, Chap. 3.

Figure 2. Calculated distributions for the volume (A) and surface area (B) of the Voronoi cells illustrated in Figure 1 Each figure shows a narrow distribution (a) with sites separated by an average distance of 16 μm and a broad distribution (b) with sites separated by an average distance of 32 μm. The areas under the two volume distributions are normalized with respect to one another. The distributions of the surface areas calculated from these volume distributions are therefore not normalized.Courtesy of Leslie Button (Corning Incorporated).

Figure 3. Calculated free energy of formation of a spherical crystallite of Mg_2SiO_4 in molten Mg_2SiO_4 as a function of crystallite radius, r, for different degrees of undercooling, ΔT, below the melting temperature, T_M [12]
ΔT, °C: a) 0; b) 10; c) 15; d) 30; e) 50 Crystallites smaller than the critical radius, r_c, redissolve in the melt.

During the crystallization hold, distortion can arise from gravitational sag of the glass or from thermal gradients in the furnace. The latter can cause one portion of the material to crystallize before the rest. Since most crystalline phases are denser than the precursor glasses, volume shrinkage of several percent is typical and must be accomplished uniformly throughout the article. Thermal gradients can arise from improper furnace design, shadow effects of refractory kiln furniture, or improper placement of glass articles. Also, the central portions of massive glass bodies are slow to heat because of their low thermal conductivity. Moreover with large articles, heat of crystallization effects can be severe: thermal waves due to exothermic crystallization of massive articles may cause the central portion to become up to 50 °C hotter than the other areas of the ceramming furnace.

To release stresses caused by differential crystallization, the apparent viscosity of the glass ceramic should be kept below 10^{12} P dur-

ing crystallization to allow viscous flow and prevent fracturing. To avoid gravitational sag, the viscosity should have a lower limit which depends on the shape and the size of the article, as well as on the support in the kiln, but is commonly around 10^{10} P.

Figure 4. Temperature regime for nucleation (a, b) and growth (c) in the $Li_2O \cdot 2\ SiO_2$ system, showing the non-coinciding temperature domains in which nucleation (low temperature) and growth (high temperature) tend to occur
a) Theoretical nucleation; b) Experimental nucleation; c) GrowthThe observed nucleation domain is characteristically narrower than the growth domain. This figure also indicates that theoretical calculations do not support the observed nucleation behavior in this system (→Glass).

3. Nature of Crystalline Phases

3.1. Metastability

The ceramming (i.e., heating) of glass to produce glass ceramics can be described as subsolidus crystallization (i.e., crystallization at a temperature below which melting occurs). Accordingly, the expected crystalline phases in glass ceramics are those of an equilibrium subsolidus assemblage appropriate for the bulk composition of the precursor glass and the temperature of the crystal growth step. However, in many glass ceramic systems, the observed crystalline phases are metastable. This is not unexpected, because glass itself is in a metastable state. Thus, with glass rather than with a melt as the initial state, crystalline phases can be formed which do not occur under conditions of "equilibrium crystallization".

Perhaps the best example of this phenomenon is the precipitation of β-quartz solid solutions from lithium aluminosilicate glasses that are cerammed for a short time at about 900 °C. Not only is the β-quartz metastable at this temperature, it also appears to be thermodynamically unstable, i.e., this phase is not a member of any equilibrium assemblage at any temperature for these bulk compositions. Prolonged heating at 900 °C, or raising the ceram temperature, causes the β-quartz glass ceramic to invert to a stable assemblage containing β-spodumene solid solution (Fig. 5). However, the early formed β-quartz glass ceramics persist indefinitely when cooled to room temperature. Moreover, such glass ceramics can withstand indefinite thermal cycling between room temperature and 900 °C without undergoing inversion to a β-spodumene glass ceramic.

Figure 5. Phase transitions in a lithium aluminosilicate glass as a function of time and temperature
All phases in this system are solid solutions (SS) with varying silica content.

3.2. Physical Properties

The physical properties rather than the morphological properties of the crystalline phases tend to dominate the behavior of a glass-ceramic article.

3.2.1. Thermal Properties

Crystalline phases encompassing a wide range of *thermal expansion coefficients* have been precipitated from glass (Table 2). Glass ceramics containing high-expansion phases such as nepheline, $NaAlSiO_4$ (expansion coefficient

50×10^{-6} K^{-1}), are commercially important because they can be strengthened by the application of low expansion glazes. Phases with coefficients of thermal expansion as high as 12.5×10^{-6} K^{-1} (e.g., fluorcanasite) can easily be precipitated from glass. Crystalline phases with ultralow coefficients of thermal expansion are even more important, however, and are widely used in glass ceramic articles that are subjected to extensive thermal cycling or articles in which even minor distortion due to thermal fluctuation is undesirable.

The most important of the low-expansion phases are the lithium aluminosilicates, β-spodumene ($LiAlSi_2O_6$) and β-eucryptite ($LiAlSiO_4$), which can be regarded as "stuffed" derivatives of the two polymorphs of crystalline silica, keatite and β-quartz, respectively. Keatite consists of a three-dimensional network of five-membered tetrahedral rings, whereas β-quartz consists of a three-dimensional network of six-membered tetrahedral rings. The helical arrangement of silica tetrahedra in both phases results in unique behavior with increasing temperature; expansion along one crystal axis is accompanied by contraction along the perpendicular axes. As a result, the net thermal expansion of both crystalline silicas is exceptionally low. To capitalize on this property in a glass ceramic body, individual crystals must be small and unoriented. Solid solutions of β-spodumene (stuffed keatite, $Li_2O-Al_2O_3-nSiO_2$) have been crystallized from a variety of lithium aluminosilicate glasses. Important in most applications of β- spodumene glass ceramics is the fact that thermal expansion can be tailored to suit a wide range of uses. Volume thermal expansions and thermal expansion for the tetragonal axes are illustrated in Figure 6 A and 6 B, respectively. Whereas bulk expansion decreases with increasing silica content, the individual axes show a very large anisotropy in expansion behavior (Fig. 6 B).

Stuffed derivatives of β-quartz show a wide range of solid solutions between SiO_2 and $LiAlO_2$, $Mg(AlO_2)_2$, $Zn(AlO_2)_2$, Li_2BeO_2, $Al(AlO_2)_3$, Li_2ZnO_2, BPO_4, or $AlPO_4$. This allows crystallization of ultralow expansion phases from a wide variety of glass compositions. The thermal expansion coefficient of β-eucryptite (lithium β-quartz solid solution) is of the order of -2×10^{-6} K^{-1}. The thermal expansion coefficient can be increased gradually by partially replacing lithium with magnesium or zinc. By taking advantage of this effect, stuffed β-quartz glass ceramics with a wide range of thermal expansion coefficients, $(-2$ to $+5)\times10^{-6}$ K^{-1} can be manufactured.

Figure 6. Thermal expansion in the lithium aluminosilicate system
A) Linear expansion for keatite (dashed lines, five-membered rings of silica tetrahedra) and synthetic β-spodumene (solid lines, 6-membered rings of silica tetrahedra;
B) Volume expansion for β-spodumene solid solutions. The n value represents the silica concentration in the $Li_2O-Al_2O_3-nSiO_2$ system.

Table 2. Bulk linear coefficients of thermal expansion of crystalline phases used in glass ceramics [14], [15]

Compound	Formula	Expansion coefficient $10^{-6}\,K^{-1}$	Temperature, °C **
Nepheline	$NaAlSiO_4$	50	RT – 500
Anorthite	$CaAl_2Si_2O_8$	19	RT – 850
Celsian	$BaAl_2Si_2O_8$	3	RT – 600
Mg cordierite	$Mg_2Al_3AlSi_5O_{18}$	7	RT – 800
Commercial cordierite		3	RT – 900
Fluorocanasite	$Ca_5Na_4K_2Si_{12}O_{30}(OH,F)_4$	12.5	RT – 800
β-Spodumene	$LiAlSi_2O_6$	2	RT – 1200
Keatite	SiO_2	−1	RT – 500
β-Eucryptite	$LiAlSiO_4$	1	RT – 450
α-Quartz	SiO_2	40	RT – 450
SiO_2 glass	SiO_2	50	−23 – 1000
α-GeO_2	GeO_2	30	RT – 850
β-Quartz	SiO_2	−6	600 – 900
Pyroxenes	$(Mg,Fe)_2Si_2O_6$	32 – 38	RT – 800
Andalusite	$Al_2Si_2O_5$	43	RT – 800
Sillimanite	$Al_2Si_2O_5$	26	RT – 800
Topaz	$Al_2SiO_4(F,OH)_2$	25	RT – 800
Zircon	$ZrSiO_4$	18	RT – 800
MgO		15.5	−150 – 1100
ZrO_2		10 – 11	RT – 1000
Al_2O_3*		9.4	−150 – 1100
TiO_2*		8.8	−150 – 1100
SiC		5.4	−150 – 1100
Diamond		4.1	−150 – 1100

* Polycrystalline samples.
** RT = room temperature.

The *specific heat* of glass ceramics varies only slightly with composition. A characteristic value in the temperature range between 20 and 400 °C is 1000 J $kg^{-1}\,K^{-1}$, and is similar to values for glass and conventional ceramics.

The *thermal conductivity* of glass ceramics is an important property in such applications as range tops and cookware. Glass ceramic materials tend to have higher thermal conductivity than glass, but lower than ceramics made from pure oxides. A characteristic value for lithium aluminosilicate glass ceramics is about 5.5 W $m^{-1}\,K^{-1}$.

3.2.2. Transparency

Most glass ceramic bodies are opaque. In order for a glass-ceramic body to be transparent either: (1) the dimension of the individual crystals should be about one third of the wavelength of visible light, or (2) the refractive index of each crystal should match the refractive index of the residual glass and the birefringence of each crystal should be negligible, (i.e., optical isotropy).

The first condition is exemplified by glass ceramics containing mullite (aluminum silicate). A fine dispersion of mullite can be formed from glasses in the Al_2O_3–SiO_2 system. The resulting glass ceramic is clear, even though mullite is birefringent and has a higher refractive index than the residual glass. Upon prolonged heat treatment, crystal size increases and is accompanied by loss of transparency.

The second condition has been achieved in a number of glass ceramics where the principal crystalline phase is the stuffed β-quartz solid solution. Pure β-quartz is an optically uniaxial positive mineral, but in solid solution its birefrigence is negligible at approximately 70 wt % SiO_2. Crystals of β-quartz containing less than 70 wt % SiO_2 are optically negative. The large number of components in the β-quartz solid solution also allow the composition of the residual glass to be tailored such that the refractive index of the crystals matches that of the residual glass, resulting in transparent glass ceramics. Compositions of commercial transparent glass ceramics are shown in Table 6.

3.2.3. Electrical Properties

Resistivity. In commercial glass ceramics, the dominant crystalline phases are silicates,

aluminosilicates, and phosphates; they can be broadly classified as electrical insulators. Electrical conduction occurs by diffusion of weakly bonded ions, primarily alkali-metal ions. At low temperatures, ionic mobility is negligible and, consequently, most of these phases are characterized by low electrical conductivity. This, coupled with the fact the crystalline phases in glass ceramics are commonly surrounded by a siliceous residual glass, is responsible for the high electrical resistivity of most glass ceramics.

Dielectric Constant. The dielectric constant of most glass ceramics is low, characteristic values being around 6 at 1 MHz and 20 °C. The structure of the crystalline phases in these materials is dominated by the rigid framework of network-forming components, such as silicate tetrahedra, which are only slightly polarized by an applied electric field. Moreover, glass ceramics in which the crystalline phases as well as the residual glass contain only network-forming components can have exceptionally low dielectric constants (as well as very high resistivity). Good examples of such materials are glass ceramics consisting of crystallites of cubic BPO_4 within a highly siliceous residual glass; they can have dielectric constants as low as 4.

Glass ceramics with relatively high electrical conductivity and/or dielectric constants can be formed from relatively depolymerized glasses, i.e., glasses with a high network modifier content. Crystallization of such glasses can result in the precipitation of oxide phases, such as titanates and niobates. For example, glass ceramics containing an interconnected network of crystallites of titanium suboxides can be formed from reduced titanium aluminosilicate glasses. These suboxides are themselves good electrical conductors and, as they are in grain-to-grain contact, make the glass ceramic itself conductive. Heat treatment of certain alkaline earth – lead aluminosilicate glasses can result in the precipitation of ferroelectric oxides with a perovskite structure. In this way, glass ceramics with dielectric constants of the order of 10^3 can be manufactured and utilized in the fabrication of capacitors.

Dielectric losses include losses through conductance, ion relaxation, deformation, and vibration. Conductance and relaxation losses are primarily determined by the mobility and concentration of the alkali-metal ions present and predominate at frequencies below 1 MHz. Deformation and vibration losses are important at frequencies of about 10 MHz. Characteristic values for glass ceramic loss factors are around 0.02 at 1 MHz and 20 °C.

Dielectric Strength. The dielectric strength is important in applications involving the use of glass ceramics as high-voltage insulators or condensers. The very fine-grained, nonporous microstructure of glass ceramics ensures that they have a substantially higher dielectric strength than conventional ceramics with characteristic values around 47 kV/mm.

3.2.4. Mechanical Properties

Glass ceramics can be considered as brittle glass – crystal composites. Their mechanical properties are strongly affected by the particle size and volume fraction of the crystalline phase, the interfacial bond strength, and differences in elastic modulus and thermal expansion between glass and crystallites.

Strength and Elasticity. Glass ceramics are stronger than the parent glasses. In glasses, theoretical strengths cannot be achieved due to the presence of intrinsic and/or extrinsic flaws. In atomic terms, flaws may be regarded as "sharp cracks" or radii that act as stress concentrators. The strength of the material is inversely proportional to the critical flaw dimension. A commonly used model developed by GRIFFITH states that

$$\sigma = (2E\gamma/\pi c)^{1/2} \tag{12}$$

where σ is the strength, E is the modulus of elasticity, γ is the fracture surface energy, and c is the length of the crack (flaw). Stress is proportional to the square root of the flaw size and cracks grow rapidly when the stress (due to mechanical or thermal loading) overcomes the atomic bonding forces that hold the material together.

For most brittle oxide solids, three types of flaw can be identified: surface cracks, internal

processing defects, (e.g., porosity), and environmentally induced damage. Strength and toughness (resistance to crack propagation) of crystalline brittle materials depend on grain boundary residual stress, the ratio of flaw dimensions to grain size, crystallite cleavage resistance, percent crystallinity, crystallite size, and relative elastic properties. Many of these issues are overcome in glass ceramics through the creation of highly crystalline microstructures which are specifically designed to resist crack propagation by increasing material toughness.

One method used to increase the toughness of glass ceramics is modification of crystallite size. If the length of the microcrack c is assumed to be proportional to the crystal diameter, then from the Griffith equation the strength σ is approximately inversely proportional to the square root of the crystal size d

$$\sigma \sim \frac{1}{\sqrt{d}} \tag{13}$$

Thus, small crystallites increase the strength of the glass ceramic.

Additional toughening occurs when the glass ceramic contains a crystalline phase that is stronger than the glass matrix. This is generally the case because, at an atomic level, the crystals which precipitate from the glass are tightly packed so that the number of bonds to be broken per unit volume is large and the modulus of elasticity is high. The size of the microcracks is then limited to the region between crystals and the critical parameter of mechanical strength will be the mean free path in the residual glass L_s:

$$L_s = d\,(1 - V_f)\,/V_f \tag{14}$$

where V_f is the volume fraction of the crystalline phase. A small mean free path indicates a major strength improvement due to deflection toughening of crack tips.

Hardness. The hardness of glass ceramics can vary significantly depending upon the composition of the crystalline phases. Knoop values in excess of 10 000 MPa can be obtained in glass ceramics where the dominant phase is magnetite (Fe_3O_4), spinel ($MgAl_2O_4$), or sapphirine ($Mg_2Al_4SiO_{10}$). This permits use of glass ceramics in applications where high abrasion resistance is required.

3.2.5. Durability

The chemical stability and durability of glass ceramics are affected by the composition of the crystalline phase, as well as the amount and composition of the residual glass. For example, a primary cause of poor chemical durability is the presence of alkali-metal ions in the residual glass. Many aluminosilicate glass ceramics contain phases that are extremely siliceous, such as β-spodumene and mullite; this results in exceptional resistance to chemical etching and staining.

3.3. Microstructure

The texture of the crystalline assemblage is one of the principal factors determining the physical properties of glass ceramics, ranking in importance only second to the physical properties of the dominant precipitating phase. Changes in the mechanism and rate of nucleation and growth affect crystal morphology, permitting the development of myriad textures, which are often distinct from normal textures characteristic of sintered powders or fusion-cast materials. Key microstructures of commercial glass ceramics are described as:

1) ultrafine-grained
2) relict
3) “coast and island”
4) “house of cards”
5) acicular interlocking
6) dendritic

Ultrafine-Grained Textures. The Voronoi patterns (Fig. 1) have shown how ultrafine-grained textures can be achieved: the greater the number of nucleation sites, the finer the precipitate and, as shown in Section 3.2, the better the mechanical strength. In the lithium aluminosilicate system, these textures can be obtained by adding roughly equivalent amounts (on a molar basis) of TiO_2 and ZrO_2 to the glass. Small ($<$10 nm) zirconium titanate crystallites precipitate when such glasses are heated to about 50 °C above the glass transition temperature. These crystallites form a uniform dispersion throughout the residual glass, providing a multitude of

nucleation sites for the epitaxial growth of the stuffed β-quartz solid solution. The efficient nucleation, coupled with sluggish grain growth, allows the crystals to grow only to about 50 nm in diameter before impinging upon one another.

Relict Textures. Some glass-ceramic microstructures mimic the texture of the precursor glass. This is, for instance, the case in mullite glass ceramics where the original glass separates into aluminous droplets within a siliceous matrix. When heated above the annealing point of the phase-separated glass, the alumina-rich droplets become more fluid than the matrix and crystallize rapidly to mullite. The mullite crystals are restricted by the shape of the original droplet and reflect its morphology. Due to the small size of the mullite "droplets" ($<0.1\,\mu$m), these glass ceramics are transparent.

Relict microstructures can also develop when a crystal phase retains the morphology of a metastable, crystalline precursor. For example, a relict dendritic texture (see below) is observed in photoetched lithium disilicate glass ceramics. The crystals reflect the dendritic texture inherited from metastable lithium metasilicate, the first crystalline phase formed upon ceramming.

"Coast and Island" Texture. A coast and island texture usually develops when an equilibrium crystal phase forms at the expense of a metastable assemblage of phases. An example is the growth of hexagonal cordierite in magnesium aluminosilicate glass ceramics at the expense of α-quartz, sapphirine, and spinel. Growth of hexagonal cordierite is initiated at boundaries between grains of the latter phases, and cordierite gradually becomes the dominant phase. Any excess silica crystallizes as cristobalite laths, which along with early-formed rutile, become partially or wholly enveloped by the cordierite. This results in an interlocking structure with good mechanical strength and toughness.

"House of Cards" Texture. The precision machinability of fluoromica glass ceramics such as Macor, with conventional metal-working tools is due to the "house of cards" texture, which is characterized by randomly oriented, flexible flakes. In the case of fluoromica glass ceramics, the plate-like crystallites have low shear strength due to their perfect basal cleavage and thus tend to either arrest fractures or cause deflection or branching of cracks. Another important property dependent on this microstructure is high dielectric strength. Such insulating qualities are possible because of the continuous interlocking of the mica sheets. Very low helium permeation rates, important in high vacuum applications, are also related to this microstructure.

Acicular Interlocking Texture. Interlocking rod- or blade-like crystals in glass ceramics can serve as important strengthening and toughening agents. Most chain silicate glass ceramics contain crystallites with this morphology. The high toughness is attributed to rod reinforcement by elongated amphibole crystals such as potassium fluororichterite.

An even tougher microstructure is developed in the highly crystalline monophase glass ceramics which consist of interpenetrating blades of fluorcanasite. Cleavage splintering can be observed, causing energy absorption through crack branching and deflection.

Dendritic Textures. The dendritic microstructure is characterized by the presence of crystallites with skeletal morphology, which is associated with very high surface energies. Snow crystals are familiar examples of dendritic crystals. Glass ceramics with dendritic textures typically contain a relatively high percentage of residual glass, due to inefficient crystal packing. The texture assumed by lithium metasilicate crystallites in the chemically etchable glass ceramic Fotoform is an example of the dendritic microstructure. The metasilicate dendrites form a continuous three-dimensional lacework. The glass ceramic can be etched with hydrofluoric acid, which attacks the low silica crystallites at a far higher rate than the durable aluminosilicate residual glass.

4. Types of Glass Ceramics

Useful glass ceramics are generally silica-containing glasses and can be classified in three groups: silicates, aluminosilicates, and fluorosilicates. Some of the more important systems currently used in the manufacture of commercial glass ceramics are shown in Table 3.

Table 3. Silicate glass ceramic systems

System	Advantages
Silicate	
Li_2O-SiO_2	photoetching capability
Aluminosilicate	
$Li_2O-Al_2O_3-SiO_2$	very low thermal expansion
$MgO-Al_2O_3-SiO_2$	good mechanical, thermal, and dielectric properties
$Na_2O-Al_2O_3-SiO_2$	high mechanical strength from compression glazing
$CaO-MgO-Al_2O_3-SiO_2$	low cost
Fluorosilicate	
$K_2O-MgO-Al_2O_3-SiO_2-F$	machinability

4.1. Silicate-Based Glass Ceramics

The compositions of some silicate-based glass ceramics are listed in Table 4.

Table 4. Composition of commercial silicate glass ceramics (mol %)

Component	Fotoform/ Fotoceram Corning 8603	"Slag-sital" white, Soviet Union	"Minelbite" gray, Hungary
SiO_2	75.8	56.3	63.8
Al_2O_3	2.2	5.0	8.8
Li_2O	17.8		
Na_2O	1.5	5.3	3.3
K_2O	2.5	0.4	1.3
MgO		3.3	8.9
CaO		27.0	10.1
ZnO [a]		1.0	
MnO [a]		0.8	1.8
Fe_2O_3 [a]		0.1	1.0
S [a]		0.8	1.2
CeO_2 [b]	0.0047		
SnO_2 [b]	0.0011		
Sb_2O_3 [c]	0.079		
Ag [a]	0.06		
Au [a]	0.00029		

[a] Nucleant.
[b] Sensitizing agent.
[c] Fining agent.

Lithium Silicates. Photosensitive lithium silicate glass ceramics (e.g., Fotoform/ Fotoceram, Corning) include a noble metal such as gold or, more commonly silver, and trivalent cerium ions (Table 4). Upon exposure to UV light, Ce^{3+} is thought to act as an electron donor, ultimately leading to the precipitation of metallic silver:

$$Ce^{3+} + h\nu \longrightarrow Ce^{4+} + e^-$$
$$e^- + T \longrightarrow T_e \quad (T = \text{trapping site})$$
$$T_e + Ag^+ \xrightarrow{\text{Heat}} Ag^0$$
$$Ag^0 + e^- + Ag^+ = (Ag^0)$$

In lithium silicate glasses, the photoinduced, thermally developed silver speck acts as a nucleation site for the epitaxial growth of dendritic metasilicate (Li_2SiO_3), which is more readily etched by hydrofluoric acid than the high-silica parent glass. Growth of lithium metasilicate occurs selectively only in those areas which have been exposed to UV radiation. Using masking techniques, complex patterns of lithium metasilicate can be formed in these glasses. The irradiation pattern can then be selectively etched out of the glass with hydrofluoric acid, forming the basis for Fotoform articles. (See also → Imaging Technology). The photoetched glass is flood-exposed to UV radiation and recerammed at higher temperature, resulting in the inversion of metastable lithium metasilicate to the stable disilicate, $Li_2Si_2O_5$. The resulting glass ceramic is strong, with an abraded modulus of rupture around 150 MPa, and negatively replicates the original irradiation pattern to a resolution of less than 0.1 mm.

Applications of such photosensitive glass ceramics include recording head pads, fluidic devices (e.g., hydraulic networks), cellular face plates for gas discharge displays, and charged plates for ink-jet printing.

Calcium and Calcium Magnesium Silicates. Blast furnace slags have been used since the 1970s in eastern Europe to manufacture inexpensive glass ceramics. Compositions of two glass ceramics of this type are given in Table 4. The furnace slags are rolled as sheets or cast as tiles and used for both interior and exterior use. The slag is remelted at around 1450 °C, formed into a glass and subsequently heat treated at about 1000 °C. The crystalline phases diopside [*14483-19-3*] ($CaMgSi_2O_6$) or wollastonite [*13983-17-0*] ($CaSiO_3$) nucleate heterogeneously on zinc, iron, or manganese sulfide particles. These alkaline-earth silicates form fine, 1 – 5 µm, equiaxial grains in a matrix of residual aluminosilicate glass, and confer good abrasion resistance and chemical durability on the glass ceramic. The glass ceramics have a va-

riety of applications depending on their composition. Their main uses are in the construction and chemical or petrochemical industries as abrasion-resistant or chemically resistant floor and wall coverings, chimneys, parts of chemical pumps, and funnels.

Magnesium Silicates. Glass ceramics based on enstatite [*14681-78-8*] ($MgSiO_3$) are of scientific interest because of the martensitic (i.e., dilatational) transformation from protoenstatite to clinoenstatite upon cooling. This transformation results in fine lamellar (i.e., parallel) twinning which produces a superior crack-tip blunting texture in the body. Dilution of enstatite glass with other components is required because pure magnesium metasilicate does not form a stable glass. Two representative compositions from the SiO_2–MgO–Al_2O_3–Li_2O–ZrO_2 and SiO_2–MgO–ZrO_2 systems are given in Table 5. These refractory, tough, fine-grained glass ceramics consist of 50–85 wt % enstatite with zircon ($ZrSiO_4$) and β-spodumene, ($LiAlSi_2O_6$), or tetragonal zirconia (ZrO_2) as additional phases.

Table 5. Compositions and properties of enstatite ($MgSiO_3$) glass ceramic

Parameter	E-1	E-2
Composition, mol %		
SiO_2	55.0	49.3
MgO	35.3	44.9
Al_2O_3	3.0	
Li_2O	1.7	
ZrO_2	4.9	5.8
Ceramming schedule	800 °C, 2 h 1200 °C, 4 h	800 °C, 2 h 1400 °C, 4 h
Abraded (modulus of rupture, MPa)	193 ± 15	200 ± 15
Fracture toughness, MPa $m^{1/2}$	3.5 ± 0.4	4.6 ± 0.6
Refractory temperature, °C	1250	1500
Coefficient of thermal expansion (0–1000 °C), K^{-1}	68×10^{-7}	80×10^{-7}

During the ceramming sequence, phase separation occurs between 800 and 900 °C and is followed by rapid crystallization of tetragonal zirconia. These zirconia crystallites form the nucleation centers on which enstatite precipitates. At temperatures above 1200 °C, zircon is formed by reaction of zirconia with unpolymerized silica present in the residual glass, thereby further stabilizing the glass ceramic.

The toughest (about 4 MPa $m^{1/2}$) and most refractory compositions are basically two-phase enstatite – zircon glass ceramics (type E-2). These have use temperatures approaching 1525 °C, the eutectic temperature in the SiO_2–MgO–ZrO_2 system. They are well-suited for high-temperature applications.

4.2. Aluminosilicate Glass Ceramics

Lithium and magnesium aluminosilicate glass ceramics are currently the principal commercial glass ceramic systems. Their utility lies in their resistance to thermal shock combined with excellent chemical durability.

The Li_2O–Al_2O_3–SiO_2 system has produced glass ceramics with exceptionally low thermal expansion coefficients based on either β-quartz or β-spodumene solid solution. These phases can be melted and quenched to a stable glass permitting the manufacture of virtually monophase β-quartz or β-spodumene glass ceramics which contain only minor amounts of nucleant phases and residual glass. Glass ceramics containing β-quartz or β-spodumene can be made from glasses of the same composition by modifying the heat treatment: β-quartz is formed by ceramming at or below 900 °C, and β-spodumene by ceramming above 1000 °C.

β-Quartz Solid Solution. The composition of the β-quartz solid solution is $(Li_2O, RO)\cdot Al_2O_3\cdot nSiO_2$, in which n varies between 2 and 10 and R is a divalent cation, commonly Mg^{2+} or Zn^{2+}; the stoichiometric end member, $LiAlSiO_4$, is called β- eucryptite. For commercial glass ceramics, n ranges between 6 and 8 because the high silica content of these compositions furnishes a melt that is sufficiently viscous to be rolled, pressed, blown, and vacuum formed. Representative compositions are listed in Table 6.

A phase with the fluorite structure, $ZrTiO_4$, has proven to be the most effective nucleating agent in precipitating β-quartz from lithium aluminosilicate glasses. Very fine crystallites with grain sizes of the order of 60 nm can be produced if the nucleant concentration is ca. 4 wt %.

The combination of transparency, low thermal expansion behavior, optical polishability,

and strength greater than glass has generated applications such as see-through cookware, telescope mirror blanks, woodstove windows, IR-transmitting range tops, optically stable platforms, and ring-laser gyros.

Table 6. Composition (mol %) of transparent glass ceramics based on β-quartz solid solution

Component	Visions (Corning)	Zerodur (Schott)	Narumi (Nippon Electric)
SiO_2	74.2	63.8	70.6
Al_2O_3	12.2	17.1	14.4
Li_2O	5.8	8.6	9.2
MgO	2.9	1.7	0.8
ZnO	0.8	1.2	
P_2O_5		3.8	0.6
F			0.3
Na_2O	0.2	0.6	0.6
K_2O	0.1		0.2
BaO	0.3		
TiO_2	2.2	2.0	1.6
ZrO_2	0.9	1.1	1.2
As_2O_3	0.3	0.2	0.4
Fe_2O_3	0.04	0.01	0.01

β-Spodumene (Keatite) Solid Solution. Two representative compositions of β-spodumene glass ceramics are given in Table 7. Comparison with the Vision composition in Table 6 indicates the similarity between β-spodumene and β-quartz glass ceramic materials.

Table 7. Composition and properties of glass ceramics based on keatite (β-spodumene) solid solution

Parameter	Corning Ware	Cercor Corning
Composition, mol %		
SiO_2	73.6	75.9
Al_2O_3	11.0	13.6
Li_2O	5.9	10.5
MgO	4.1	
ZnO	0.8	
Na_2O	0.4	
K_2O	0.1	
TiO_2	3.7	
ZrO_2	0.1	
Fe_2O_3	0.1	
As_2O_3	0.2	
Coefficient of thermal expansion, K^{-1}	1.2×10^{-6} (0–500 °C)	0.5×10^{-6} (0–1000 °C)
Abraded flexural strength, MPa	100	

Corningware is made from a multicomponent glass containing TiO_2 as nucleating agent. The ceram schedule attains a maximum near 1125 °C, about 100 °C below the liquidus temperature. At least 93 vol % of the material is crystalline, with β-spodumene being the dominant phase. Spinel, rutile, and residual glass are secondary phases. The glass ceramic is produced as a honeycomb product for a turbine engine heat exchanger. It is made from a powdered glass frit, which as slurry impregnates paper wound on a wheel as alternately corrugated sheets. After firing, a porous ceramic regenerator wheel is produced which allows energy to be transferred from hot exhaust gases to the cold intake air in the turbine engine.

Cordierite-Based Glass Ceramics. The hexagonal (high temperature) polymorph of cordierite [*1302-88-1*] ($Mg_2Al_4Si_5O_{18}$) is the principal crystalline phase in magnesium aluminosilicate glass ceramics. These materials are strong, have excellent dielectric properties, and good thermal stability and shock resistance. The thermal expansion of cordierite is low and anisotropic, the c axis expanding, and the a and b axes contracting, resulting in virtually zero volume expansion.

In these materials, hexagonal cordierite crystallizes together with cristobalite, rutile, and magnesium dititanate; a small amount of residual glass is isolated at the grain boundaries. This glass ceramic is used for missile radomes. A representative glass ceramic composition, together with selected physical properties, is shown in Table 8.

Table 8. Composition and properties of commercial cordierite glass ceramic (Corning 9606)

Parameter	Value	Phases
Composition, mol %		
SiO_2	58.1	
Al_2O_3	12.1	
MgO	22.6	cordierite
CaO	0.1	cristobalite
TiO_2	6.9	rutile
As_2O_3	0.1	Mg-dititanate
Fe_2O_3	0.1	
Coefficient of thermal expansion, K^{-1}	4.5×10^{-6}	
Fracture toughness, MPa $m^{1/2}$	2.2	
Thermal conductivity, $J\,s^{-1}\,cm^{-1}\,K^{-1}$	0.37	
Knoop hardness, MPa	7000

Loss tangent	0.0003	

Sodium Aluminosilicates. Fine-grained glass ceramics, containing nepheline [*12251-27-3*] ($NaAlSiO_4$) can be formed from glasses in the $Na_2O-Al_2O_3-SiO_2-TiO_2$ system. Nepheline is a stuffed derivative of tridymite, a high-temperature polymorph of silica. Titanium dioxide acts as an internal nucleating agent and opacifier, and crystallizes as anatase in the cerammed material. These glass ceramics have thermal expansion coefficients around 5×10^{-6} K^{-1}, near that of nepheline, reflecting the expansion behavior of tridymite. A typical composition of this glass ceramic is given in Table 9.

Table 9. Nepheline glass ceramic tableware (Pyroceram 9609)

Oxide	Content, mol %	Phases
SiO_2	53.0	
Al_2O_3	21.4	
Na_2O	16.0	nepheline ($NaAlSiO_4$)
BaO	2.6	celsian ($BaAl_2Si_2O_8$)
TiO_2	6.0	anatase (TiO_2)
As_2O_3	0.4	glass

Barium is added to promote the formation of celsian ($BaAl_2Si_2O_8$), which has a lower thermal expansion coefficient (3×10^{-6} K^{-1}) than nepheline, thereby improving thermal shock resistance. The glass ceramics are used in a wide variety of products ranging from coverings for microwave antennas, large electric insulators, and miniature vacuum tubes to heat-resistant kitchenware and stove hotplates.

Other Aluminosilicate Systems. Glass ceramic systems based on mullite [*55964-99-3*] ($3Al_2O_3\cdot 2SiO_2$) can be produced from modified binary $Al_2O_3-SiO_2$ glasses. Transparent mullite glass ceramics, doped with ions such as Cr^{3+} have unique luminescent characteristics.

Calcium aluminosilicate glass ceramics based on anorthite [*1302-54-1*] ($CaO\cdot Al_2O_3\cdot 2SiO_2$) can be formed by surface crystallization sintering of glass frit. They form ideal glass ceramic matrices for silicon carbide fiber-reinforced composites. The good thermal stability of anorthite (up to 1500 °C), combined with its close match in thermal expansion with silicon carbide makes this composition particularly attractive.

Glass ceramics belonging to the *cesium aluminosilicate system* are highly refractory. Glass ceramics made from pollucite [*1308-53-8*] ($Cs_2O\cdot Al_2O_3\cdot 4SiO_2$) and mullite crystallized at 1600 °C have a thermal stability that is 350 °C higher than that of fused silica. Due to their refractory nature, these materials must be melted at 1900 °C and formed near 1800 °C.

4.3. Fluorosilicate Glass Ceramics

Two classes of glass ceramics fall in this category: (1) fluorosilicate micas consisting of sheets of silica tetrahedra and (2) fluoroinosilicates, whose structure is based on double or quadruple chains of silica tetrahedra.

Fluormica Glass Ceramics. Fluormica sheet silicates provide machinable glass ceramics which can be turned, drilled, milled, or threaded using conventional metal-working machines.

Macor is a commercial glass ceramic based on fluorophlogopite [*12003-38-2*] ($KMg_3AlSi_3O_{10}F_2$). Due to its high fluorine content, stable glasses with fluorophlogopite composition cannot be formed. Addition of B_2O_3 and SiO_2, as shown in Table 10, results in stable glass. The Macor composition is melted to an opal glass that is subsequently crystallized by heating to 950 °C. During ceramming, metastable chondrodite, $2\,Mg_2SiO_4\cdot MgF_2$, is the first phase to precipitate from the glass, crystallizing from the magnesium-rich matrix at the surface of the aluminosilicate droplets that constitute the rest of the parent opal. Chondrodite is subsequently transformed into norbergite, $Mg_2SiO_4\cdot MgF_2$, which in turn reacts with the residual glass to form fluorophlogopite and some mullite.

The mica structure is particularly well adapted for machinability due to the rapid propagation of fracture in the plane of the silica sheets. Furthermore, the "house of cards" texture of fluorophlogopite glass ceramics (see Section 3.3) increases the tortuosity of the fracture path and, hence, fracture energy is rapidly dissipated. The machinability of Macor also benefits from the relatively coarse size of the mica flakes. Glass ceramics with small crystallites are less easy to machine than those with large crystallites; the

difference is presumably due to the additional energy required to cleave many more crystallites.

Table 10. Commercial fluormica glass-ceramic compositions (mol %)

Oxide	Macor	Dicor
SiO_2	42.2	46–57
B_2O_3	6.6	
Al_2O_3	8.8	0–1
MgO	19.3	22–23
K_2O	5.4	8–9
F	17.8	13–21
ZrO_2		0–1
CeO_2		0.02
Mica type		
Macor	$K_{1-x}Mg_3Al_{1-x}Si_{3+x}O_{10}F_2$	
Dicor	$K_{1-x}Mg_{2.5+x}/2Si_4O_{10}F_2$	
	$x < 0.2$	

Macor has been employed in a wide range of applications, including precision electrical insulators, vacuum feedthroughs, windows for microwave tube parts, sample holders for field ion microscopes, seismograph bobbins, gamma-ray telescope frames, and boundary retainers on the space shuttle. The precision machinability of Macor with conventional metal-working tools, its high dielectric strength (40 kV/nm), and very low helium permeation rates are particularly important in high-vacuum applications.

Fluorosilicate glass ceramics based on tetrasilicic micas, such as $KMg_{2.5}Si_4O_{10}F_2$, have been developed for use in dental restoration. Tetrasilicic fluormica glass ceramics, marketed under the trade name Dicor, have improved chemical durability and translucency relative to Macor. Good strength ($\sim$150 MPa) is associated with the development of anisotropic flakes at relatively high temperature ($>$1000 °C). Translucency is achieved by nearly matching the refractive indices of the fluormica and residual glass, while simultaneously maintaining a fine ($\sim$1 µm) crystal size. Cerium is added to simulate the fluorescent character of natural teeth. The glass ceramic may be cast accurately using a lost wax technique and conventional dental laboratory molds. The high strength and low thermal conductivity of these materials provide advantages over conventional metal–ceramic systems.

Chain Fluorosilicates. Natural nephrite-jade is renowned for its toughness (i.e., resistance to fracture) due to crack tip blunting by randomly oriented acicular crystallites. Two chain fluorosilicates can produce glass ceramics with similar high toughness: potassium fluorrichterite and fluorcanasite.

Potassium Fluorrichterite. The crystal structure of potassium fluorrichterite $KNaCaMg_5Si_8O_{22}F_2$, consists of double chains of silica tetrahedra. An optimized fluorrichterite glass-ceramic composition in mole percent is:

SiO_2	59.2
Al_2O_3	1.1
MgO	18.5
CaO	4.4
Na_2O	2.5
K_2O	2.7
Li_2O	1.3
BaO	0.1
P_2O_5	0.4
F	9.7

In the early stages of the ceramming of a fluorrichterite glass, an amorphous emulsion is formed in which one of the two phases has a similar composition to tetrasilicic fluormica, $K(Mg_{2+x}Li_{1-2x})Si_4O_{10}F_2$. This phase crystallizes rapidly at 600 °C and incorporates most of the network modifiers in the system, thereby significantly increasing the viscosity of the residual glass. Precipitation of diopside ($CaMgSi_2O_6$) follows above 700 °C. Fluormica and diopside subsequently react above 850 °C with the residual glass to produce the stable assemblage potassium fluorrichterite and cristobalite, the latter phase growing above 900 °C.

The residual glass is enriched in silica, alumina, and P_2O_5, resulting in exceptional overall chemical durability. The high thermal expansion coefficient of this glass ceramic allows the development of compressive strength through conventional glazing techniques. Thus, the flexural strength of these glass ceramics (150 ± 15 MPa) can be increased to 200 ± 15 MPa. Glazed fluorrichterite glass ceramics have a translucency and gloss comparable to those of bone china. This glass ceramic is currently being manufactured as high-performance institutional tableware and mugs for the retail Corelle line.

Fluorcanasite Glass Ceramics. Fluorcanasite, $Ca_5Na_4K_2Si_{12}O_{30}(OH,F)_4$, has a crystal

structure that is characterized by four interconnected silica chains running parallel to the b axis, thereby forming a tube. Potassium and sodium ions are located centrally in the tubes, which are interconnected by a network of edge-sharing, calcium and sodium oxyfluoride octahedra.

Fluorcanasite has been crystallized from glasses. It is nucleated by crystallites of CaF_2 and grows in spherulitic fashion on these nuclei. Fluorcanasite glass ceramics can be highly crystalline and virtually monophase. They have flexural strengths near 300 MPa, a modulus of elasticity near 80 GPa, and a thermal expansion coefficient near $12.5 \times 10^{-6}\ K^{-1}$. The strain rupture is about 0.35, a high value for a silicate material. The measured fractured toughness is $5.0\ MPa\ m^{1/2}$, indicating a fracture surface energy of approximately $150\ J/m^2$, higher than that for natural nephrite-jade.

Glass with a fluorcanasite composition can be rolled, pressed, or cast. Ceramming can be completed below 900 °C in less than 1 h. Due to their low silica content, fluorcanasite glass ceramics are inferior in chemical durability to soda – lime glass, but superior to many other building materials. Potential applications for fluorcanasite glass ceramics include architectural cladding, interior partitioning, thin housewares, and magnetic memory disk substrates.

Fotoform, Fotoceram, Visions, Corning Ware, Cercor, Pyrocam, Macor, Dicor, Corelle, Zerodur, and Narumi are registered trade marks.

1. Introduction

D-Gluconic acid [*526-95-4*], 1,2,3,4,5-pentahydroxy pentane-1-carboxylic acid, $C_6H_{12}O_7$, M_r 196.16, was discovered in 1870 by Hlasiwetz and Habermann during the oxidation of glucose with chlorine. The substance was isolated in the form of its barium and calcium salts. Several authors subsequently reported that gluconic acid could be obtained by treatment of various mono-, di-, and polysaccharides with oxidizing agents such as elemental halogen, copper(II) or hexacyanoferrate(III) salts, or mercury(II) oxide. Depending on the type of sugar and the oxidant employed, byproducts of the reaction include formic acid, glycolic acid, oxalic acid, and carbon dioxide.

As early as 1880 Boutroux recognized that gluconic acid was produced, together with acetic acid, by the oxidative action of *Acetobacter aceti* on glucose. This characteristic was also found to be associated with numerous other bacteria [1]. Molliard was the first to report the presence of gluconic acid in cultures of *Sterigmatocystis nigra*, now known as *Aspergillus niger* [2]. The currently preferred method for preparing gluconic acid and its derivatives with the aid of *Aspergillus* strains is based on the work of a number of authors [3]. The catalytic activity of the enzyme glucose oxidase was first described by Müller [4].

During the 1930s anodic oxidation was suggested for the preparation of calcium gluconate [5]; proposals for catalytic oxidation of glucose with the aid of air or oxygen followed somewhat later [6].

Sources. Gluconic acid is a naturally occurring substance in humans and other organisms (cf. Chap. 7); it is found in food products such as wine and honey.

2. Physical Properties

Free D-gluconic acid is difficult to prepare in crystalline form. According to Milsom and Meers [7], crystallization of the anhydrous substance is possible below 30 °C, and a monohydrate has been reported to crystallize at 0 – 3 °C with a characteristic crystalline structure, *mp* ca. 85 °C [8].

Anhydrous gluconic acid is a white, odorless, crystalline powder, specific rotation $[\alpha]_D^{20}$ $-6.7°$ [9], $[\alpha]_D^{25}$ $-5.4°$ [10].

Literature values for the melting point of gluconic acid fall in the range 120 – 131 °C. The spread in values is due to the formation of intramolecular anhydrides whose presence lowers the melting point.

Two *lactones* of gluconic acid are known. These exist both in the solid state and also in aqueous solution, where they are in equilibrium with each other and with the free acid.

This complex equilibrium is also influenced by the dissociation of the free acid, which has a

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a12_449

reported [10] dissociation constant K_A at 25 °C of 1.99×10^{-4} and a pK_A of 3.70 (3.62 according to [11]).

Lactone hydrolysis and formation are both first order with respect to hydrogen ion concentration, with rate constants (k and b, respectively) related as follows [12]:

$$k_{1,5}+b_{1,5}=c_{H^+}\cdot 5.5\times 10^{-2}\,s^{-1}$$
$$k_{1,4}+b_{1,4}=c_{H^+}\cdot 4.3\times 10^{-4}\,s^{-1}$$

Thus, equilibrium is established with the 1,5-lactone roughly 100 times faster than with the 1,4-lactone. The following empirical equation describing the kinetics of hydrolysis for the 1,5-lactone in the pH range 0.6 – 8.2 has been reported [12]:

$$k_{1,5}=c_{H^+}\cdot 4.7\times 10^{-2}+c_{OH^-}\cdot 4\times 10^{3}$$
$$+2.5\times 10^{-4}\,s^{-1}$$

This expression indicates that the OH^- ion strongly catalyzes the opening of the lactone ring, while the H^+ ion is considerably less effective. In the region of neutrality, hydrolysis is quite slow. The rate of hydrolysis over the narrower pH range 3 – 5 is given by

$$-dc_L/dt=kc_L$$

where c_L is the concentration of the 1,5-lactone and $k=2.3\times 10^{-4}\,s^{-1}$. The activation energy for the process is reported to be 62.8 kJ/mol [13].

Gluconic acid is quite soluble in water. At 20 °C, commercial 50 % gluconic acid solution has a pH of 1.82 and a density of 1.23 g/cm^3. In this concentration region, solution density increases almost linearly with increasing concentration. The acid is only slightly soluble in ethanol and virtually insoluble in nonpolar solvents.

Storing gluconic acid over a desiccant at room temperature or heating it above 50 °C leads to the formation of lactones. Pyrolysis occurs above 200 °C.

Gluconic acid 1,5-lactone [*90-80-2*] is a white, crystalline substance with a faintly sweet taste, *mp* 153 °C, $[\alpha]_D^{20}$ +66.2 ° [13]. On standing, both the pH and the specific rotation of a lactone solution decrease as a result of hydrolysis, becoming constant only after equilibrium is established. Approximately 90 g of 1,5-lactone dissolves in 100 mL of water at 20 °C; this increases to about 205 g at 50 °C. Only small amounts dissolve in organic solvents. The *1,4-lactone* [*1198-69-2*] crystallizes as fine needles, *mp* 134 – 136 °C, $[\alpha]_D^{20}$ +67.8 ° [13].

3. Chemical Properties

The action of oxidizing agents such as nitric acid or hydrogen peroxide on either the lactones or the calcium salt of gluconic acid leads under mild conditions to mixtures of oxogluconic acids, with the carbonyl groups at the 2- and the 5-positions. 2-Oxo-D-gluconic acid [*669-90-9*] is the principal product of anodic oxidation, oxidation with sodium chlorate in acid solution, or fermentation by species such as *Acetobacter suboxydans, A. xylinum,* or *A. gluconicum.* Treatment with concentrated nitric acid or with N_2O_4 results in formation of glucaric acid, $HOOC(HCOH)_4COOH$ [*87-73-0*].

Hydrogenation of gluconic acid in aqueous solution over a platinum oxide catalyst results in a modest yield of D-glucose, whereas the 1,5-lactone undergoes this reaction in high yield. Refluxing with concentrated hydriodic acid in the presence of red phosphorus causes reduction to hexanoic acid [*142-62-1*].

The six functional groups of gluconic acid can, in principle, react with a variety of reagents, such as alcohols, acids, etc. Nevertheless, the resulting derivatives tend to be stable only if reaction is complete. Partial reaction leads to nonuniform mixtures that are sensitive to hydrolysis; such reactions have little significance.

In contrast, considerable interest exists in the ability of gluconic acid and its alkali salts to form complexes with polyvalent cations; some of these complexes are very stable (see Chap. 5). Nuclear magnetic resonance spectra suggest that complex formation involves both the carboxyl and the hydroxyl groups.

4. Production

For commercial purposes, D-gluconic acid and its salts are prepared exclusively by the oxidation of glucose or glucose-containing raw materials. The oxidation method may be chemical, electrolytic, catalytic, or biochemical.

4.1. Chemical Oxidation

Chemical methods have the disadvantage of limited specificity even under carefully controlled and optimized reaction conditions, which results in unsatisfactory yields (60 – 80 %) and undesirable byproducts. Isolation and purification of the product are correspondingly difficult. Hydrogen peroxide [14], ozone [15], and oxygen [16] have been the oxidants of choice, presumably because of ecological problems associated with other oxidizing agents and their reduction products.

4.2. Electrochemical Oxidation

Similar problems accompany electrochemical procedures, most of which are based on the oxidation potential of halogens. The usual approach is to electrolyze a glucose solution containing bromide (ca. 10 mol % relative to glucose) at a current density of 1 – 20 A/dm^2. Carbonates (preferably calcium carbonate) or hydroxides are added to neutralize the resulting acid [17]. Electrical current yields are 80 – 86 %; the product yield based on glucose is 80 – 97 %. The rapid increase in the cost of electricity in recent years has made the electrolytic process noncompetitive.

4.3. Catalytic Oxidation

In contrast, recent developments have led to great improvements in the technique of oxidizing glucose with oxygen or air and serious consideration has been given to adopting this strategy on an industrial scale. Oxidation is carried out, with the aid of an appropriate catalyst, on a glucose solution whose concentration is 1 – 2 mol/L. The pH is held between 8 and 11 (preferably 9 – 10) by continuous addition of alkaline solution.

The catalysts originally employed were finely divided platinum-group metals suspended on activated charcoal, aluminum oxide, or some other carrier [18]. The corresponding reaction mechanism for a Pt – C catalyst has largely been elucidated [19].

The most important observations with respect to the catalytic reaction include a rapid decrease in activity of the catalyst from its initial levels (a decline that cannot be completely reversed despite efforts at reactivation), the need for highly purified glucose solutions, and the formation of various byproducts as a result of insufficient catalyst specificity and the tendency of the substrate to undergo side reactions under the prevailing reaction conditions.

The foregoing disadvantages have been circumvented through a series of developments with respect to the catalysts employed. Thus, platinum-group metals have been found to become more active and more selective if they are doped with lead [20], [21], selenium [22], thallium [21], or bismuth [21], [23]. The preferred carrier is activated charcoal.

The catalyst described in [23] permits conversion of a 2 M glucose solution to gluconic acid with oxygen at 50 ± 1 °C and pH 9.5 ± 0.2 (neutralization with 40 % sodium hydroxide solution) in >99.5 % yield within 1 h. The process is also highly selective: product purity (based on sodium gluconate) is >99.5 %. In addition, no special effort need be taken to purify the glucose solution. Loss of catalytic activity is minimal, permitting the catalyst to be recycled many times without an intervening reactivation step.

The economic viability of the process depends largely on the activity, selectivity, lifetime, and cost of the catalyst, as well as on the measures required for product purification and the energy demands.

Despite earlier suggestions to the contrary, glucose cannot be oxidized photochemically to gluconic acid [24].

4.4. Methods Involving Biotechnology

The principal organisms employed today for large-scale biological preparation of gluconic acid are *Aspergillus niger* and *Gluconobacter suboxydans.*

Aspergillus Niger Process. The biochemistry of gluconic acid formation by *Aspergillus niger* is illustrated in the following diagram [25], [26]:

where FAD and $FADH_2$ are the oxidized and reduced forms, respectively, of flavine – adenine dinucleotide. β-D-Glucose is oxidized catalytically to glucono-1,5-lactone by the enzyme glucose oxidase (see also → Enzymes). Subsequent hydrolysis of the lactone to gluconic acid is to some extent spontaneous, but the enzyme gluconolactonase also plays a role.

Glucose oxidase (E.C. 1.1.3.4) [*9001-37-0*], M_r 186 000, contains two FAD moieties as prosthetic groups. These are responsible for the abstraction of hydrogen atoms from glucose (to form $FADH_2$), which ultimately combine with oxygen to produce hydrogen peroxide. This is in turn cleaved to water and oxygen by the enzyme catalase. Both glucose oxidase and catalase are present as endoenzymes in the fungal mycelium [27], [28].

In addition to glucose oxidase, *Aspergillus niger* may have other enzymes that also lead to gluconic acid formation, comparable to the glucose dehydrogenase and phosphomonoesterases found in *A. oryzae* [29], [30].

Metabolic investigation has shown fermentation to be a three-stage process [31]: a brief lag phase, followed by an acceleration phase during which glucose oxidase activity rises nearly logarithmically, and finally a stationary phase, which is characterized by a constant rate of gluconic acid formation. The optimum pH for the reaction lies near 5.6 [32].

Production Parameters. Fermentative synthesis of sodium gluconate requires a sterilized substrate; a typical formulation is as follows: glucose 250 – 350 g/L, $MgSO_4 \cdot 7H_2O$ 0.2 – 0.3 g/L, KH_2PO_4 0.2 – 0.3 g/L, and $(NH_4)_2HPO_4$ or urea 0.4 – 0.5 g/L. The substrate may be sterilized either in batches at 110 °C with a residence time of 45 min or continuously under conditions providing several minutes exposure to a temperature of 135 – 150 °C. The sterile medium is then transferred to the fermentation vessel, adjusted to a pH of 4.5 – 5.0, and inoculated with cultured microorganism.

The culture medium contains only about 100 g of glucose per liter, but as much as twice the above amounts of nutrient salts, an increased level of nitrogen compounds, and a growth-stimulating additive consisting of 0.2 – 0.4 g of corn steep powder (a residue obtained by evaporating the water in which maize has been soaked). A lyophilized permanent culture is used to grow the conidia. This culture is first activated with a specific growth medium in culture tubes. After several subcultures have been prepared, the organism is introduced into a culture flask

containing a special medium that encourages the formation of conidia. After an incubation period of 5 – 10 d the conidia are harvested, either in dry form or as an aqueous suspension, and used to inoculate the preculture.

During the production phase, the system is maintained at 30 – 32 °C and pH 5.5 – 6.5. The pH is controlled by continuous neutralization with 30 – 50 % sodium hydroxide solution, the consumption of which is an indication of reaction progress. Depending on the starting concentration of glucose, fermentation continues for a period of 40 – 100 h. Under conditions of maximum specific rate of product formation, 20 – 30 mmol of gluconic acid is generated per hour for each gram of biomass (dry weight) [33], [34].

After fermentation is complete, the microorganisms are removed by filtration and washed. The filtrate is decolorized with activated charcoal, subjected to fine filtration, and then either evaporated and crystallized or directly spray-dried.

The fungal mycelium residue may be used for the isolation of glucose oxidase or it may simply be burnt [35].

Various attempts have been made to use mathematical models to optimize the above process [33], [34], [36], [37]. These efforts have shown that both the specific rate of oxygen uptake and the specific rate of formation of gluconic acid increase approximately linearly with increasing concentration of dissolved oxygen or increasing oxygen partial pressure. If the effects of the brief growth phase and retentive metabolism are ignored, the productive phase follows simple Michaelis – Menten kinetics, with K_M 3.6×10^{-4} mol/L at 33 °C and pH 6.6 [34]. At 25 °C and pH 5.6, $K_M = 2.0 \times 10^{-4}$ mol/L [32]. Isolated glucose oxidase under these conditions has K_M 4.8×10^{-4} mol/L.

To ensure economically viable yields of more than 80 %, an adequate oxygen supply (0.1 L of oxygen per liter of solution per minute) must be maintained, and gas distribution within the fermentor must be optimized. The oxygen partial pressure may be increased by conducting fermentation at elevated pressure or by employing air enriched in oxygen [38].

Product concentration in the fermentation solution can be increased if glucose is introduced at a higher concentration and pH control is discontinued near the end of the fermentation [39]. These conditions result in formation of a mixture of sodium gluconate and free gluconic acid, which has a considerably higher solubility than the salt alone. Such a solution (e.g., Naglusol) is suitable for commercial use in technical applications as soon as the mycelium has been removed.

Gluconobacter Suboxydans Process. The *Gluconobacter suboxydans* process is rather different, in that conversion of β-D-glucose to glucono-1,5-lactone occurs through the action of two glucose dehydrogenases: a particulate quinoprotein glucose dehydrogenase and a soluble NADP-dependent glucose dehydrogenase [40], [41].

Gluconobacter suboxydans fermentation is distinguished by a high affinity for oxygen relative to the *Aspergillus* process: simple aeration suffices to ensure a high rate of glucose conversion. In addition, the process displays greater tolerance with respect to acidity, permitting the isolation of free gluconic acid directly from the fermentation solution [42].

Other Methods. Another approach that leads directly to gluconic acid uses acidophilic methylotropic bacteria (*Acetobacter methanolicus*) under nonsterile conditions [43]. Other procedures have been described that involve immobilized enzymes, microorganisms, or both [44–47]. To date, none of these methods is used for commercial production of gluconate, largely because of rapid deactivation of the enzymes or limitations with respect to oxygen diffusion.

Downstream Processing. Ordinary commercial grades of free gluconic acid may be prepared from the corresponding sodium salt either through cation exchange or electrodialysis. Passage of a mixture of sodium gluconate and free gluconic acid over a strong anion-exchange resin results in adsorption of gluconate [48].

Glucono-1,5-lactone crystallizes from a supersaturated aqueous gluconic acid solution between 36 and 57 °C [49]. A two-step continuous crystallization is said to result in increased productivity per unit volume under conditions that are favorable in terms of energy consumption [50]. In the first step, a crystalline suspension (3 – 10 % crystalline material) is produced in a supersaturated gluconic acid solution held at

65 – 75 °C. The second step involves controlled cooling to 40 – 45 °C, followed by a period of crystal maturation at constant temperature. A portion of the resulting crystalline suspension is then recycled to the first step.

According to [51], the 1,5-lactone may also be obtained from an aqueous gluconic acid solution by dehydration involving azeotropic distillation with alcohols, followed by crystallization from the alcohol-containing residue.

Crystallization above 70 °C leads to the 1,4-lactone.

5. Uses

The primary applications of gluconic acid follow from its most important characteristic: it is a weak acid capable of dissolving the oxides, hydroxides, and carbonates of polyvalent cations without attacking metallic or nonmetallic surfaces. The value of this property is further enhanced by the fact that the acid forms water-soluble complexes with such cations. Gluconic acid is thus exceptionally well suited for use in removing calcareous and rust deposits from metals or other surfaces, including beer and milk scale on galvanized iron, magnesium alloys, or stainless steel. The compound is also used in the textile industry together with magnesium salts as a stabilizer for peroxide bleach baths.

Because of its physiological properties, D-gluconic acid has also been used in both the food and beverage and the pharmaceutical industries. Thus, low concentrations (0.02 – 0.1 %) of the substance effect the inversion of sucrose without causing the resulting fructose to undergo further reaction. Trace elements are usually administered in the form of gluconate salts because such compounds are readily absorbed into the body and are well tolerated. Potassium gluconate also has certain pharmaceutical applications and may be dispensed either in anhydrous form or as the monohydrate.

In many applications, gluconic acid 1,5-lactone is a convenient substitute for the free acid. The lactone offers particular advantages in circumstances involving acidic conditions over a long period, e.g., in the preparation of pickled goods and frankfurter-type sausages, or in curing fresh sausage. Another example is its use as a leavening agent in baked goods.

The most common gluconate is sodium gluconate, M_r 218.14, $[\alpha]_D^{25}$ +12.0° [10], whose solubility behavior is as follows:

t, °C	0	20	50	80	100
c, g/100 g H_2O	43	60	85	133	160

Sodium gluconate, like the free acid, forms complexes with metal cations. The stability of such complexes often increases considerably with increasing pH [13]. This salt also displays cleansing characteristics with respect to surfaces of widely varying type and structure.

Combinations of sodium gluconate with sodium carbonate or sodium hydroxide solution are useful for removing grease and corrosion from aluminum, rust from steel, oxide coatings from copper and copper alloys, and for etching aluminum. Strongly alkaline gluconate baths permit the removal of zinc coatings from metallic objects, castings, and scrap metal. Such baths are characterized by a high zinc capacity and a correspondingly long life.

Alkaline sodium gluconate solutions at 95 – 100 °C are effective agents for the rapid removal of paint and varnish, without damaging underlying surfaces. Gluconate is also useful in the pretreatment of certain surfaces, e.g., in the galvanic deposition of nickel – cobalt brazing surfaces onto aluminum or in the baths required for preparing smooth, shiny surface platings of nickel, tin, and zinc. In the latter application, gluconate is increasingly used to replace the highly toxic cyanide ion.

Mixtures of gelatin and sodium gluconate are used as sizing agents in the paper industry because they result in a product with increased acid resistance. Textile manufacturers employ gluconate (sometimes in combination with polyphosphates) for desizing polyester or polyamide fabrics and for finishing natural cellulose fibers.

Sodium gluconate is a component of commercial cleansers because of its absolute stability to hydrolysis at high temperature and high pH, as well as its sequestering properties with respect to hardening agents in water. For example, sodium gluconate is used in bottle washing and in cleaning aluminum surfaces (e.g., building facades, aircraft, and containers).

Concrete manufacturers have found sodium gluconate to be a highly effective agent for retarding the curing process. Addition of 0.02 – 0.2 wt % of this substance (relative to cement) produces a very homogeneous concrete with high resistance to water, frost, and cracking. This material is also easily worked and shows increased stability upon setting. Other advantages accompanying the introduction of gluconate include better flow properties for the wet concrete mixture, increased wettability with respect to iron reinforcing structures, and maintenance of plasticity despite reduced water content.

Relative to other organic and inorganic complexing agents, gluconic acid, its lactone, and its salts offer one major advantage: they are all destroyed effectively and quickly by biological wastewater treatment, whether adapted or not. The same applies [52] to the soluble complexes of gluconate with aluminum, copper, iron, and zinc, although biodegradation of the chromium gluconate complex occurs more slowly. Metal ions released during gluconate complex degradation are largely removed from the purified wastewater, either by precipitation or by adsorption on the sludge. This circumstance reduces a major threat that might appear to accompany the use of gluconate as a complexing agent: mobilization or remobilization of heavy metals into surface water [53].

Destruction of heavy-metal gluconate complexes in wastewater may occur not only through biodegradation but also by simple hydroxide precipitation [54], in which iron(III) acts as a precipitant at a pH of 9 – 10; see also [55].

6. Economic Aspects

Annual worldwide production capacity for gluconic acid and its derivatives is estimated to be 60 000 t. The bulk of production (85 %) is in the form of sodium gluconate and other alkali gluconate salts. Present consumption levels are, however, significantly lower, resulting in only 60 – 70 % utilization of existing capacity. Principal manufacturers include: Akzo-Chemie, Amersfoort, Holland; Biochemie Ladenburg, Ladenburg, Federal Republic of Germany; Finnish Sugar Co. Ltd., Espoo, Finland; Fujisawa Pharmaceutical Co., Osaka, Japan; Pfizer, New York, New York; Roquette Frères, Lille, France.

7. Physiology, Product Specifications

D-Gluconic acid and its 1,5-lactone are important intermediates in carbohydrate metabolism. These compounds serve two important functions: (1) they contribute to the synthesis of reduced nicotinamide – adenine dinucleotide phosphate (NADPH), which is required in the biosynthesis of fatty acids and steroids, and (2) they lead to the formation of ribose 5-phosphate, which is used in nucleic acid synthesis [56].

The gluconate salts of sodium [*527-07-1*] calcium [*299-28-5*], copper [*13005-35-1*], iron(II) [*299-29-6*], and manganese [*6485-39-8*] are on the list of GRAS substances [57], [58]. The gluconates of potassium [*299-27-4*], magnesium [*3632-91-5*], and zinc [*4468-02-4*] have not been shown to have teratogenic, mutagenic, or carcinogenic properties [56].

Under the food and beverage law of the Federal Republic of Germany, D-gluconic acid is classified as a foodstuff and not regarded as an additive. Purity standards for gluconate salts are prescribed in the U.S. Food Chemical Codex (FCC III) of 1981, the U.S. Pharmacopeia (1985), and the European Pharmacopeia. Methods of analysis can be found in [32] and [59].

1. Introduction and History

The saccharides are among the most common organic compounds found in nature and glucose is by far the most abundant monosaccharide. D-Glucose (D-glucopyranose) [*50-99-7*], $C_6H_{12}O_6$, M_r 180.159, is the primary six-carbon sugar (hexose) found in the juice of most fruits and berries. Starch (→ Starch) and cellulose (→ Cellulose) are composed of anhydroglucopyranose units connected through α- and β-linkages, respectively, to form long-chain polymers. Thus, a considerable portion of the human diet is composed of glucose in either the free or the polymerized state.

When α-linked polymers of glucose (starch) are ingested, acid and enzymatic processes convert these macromolecules to glucose in much the same way that it is made commercially. The digestive process begins in the mouth with the action of salivary amylase. Final digestion is accomplished by the action of numerous other enzymes in the small intestine.

D-Glucose was probably known to early humans because it appears as granules in honey due to crystallization. However, despite the abundance of glucose in nature, the disaccharide sucrose has historically been the primary sweetener for humans. Sucrose is sweeter than glucose, and very pure crystals can be recovered from syrups extracted from sugar cane and sugar beets (→ Sugar).

Most glucose, on the other hand, is bound up as starch, requiring complicated manufacturing processes to release its sweetness. The growth of the glucose sweetener industry has been based upon a classic response to market needs for improved purity and functionality.

Pure glucose was first obtained from grape juice by the German chemist A. S. MARGGRAF in 1747 [1]. PROUST was one of the first to precipitate α-D-glucose crystals from grape juice in 1801 [2]. The synonym for D-glucose, grape sugar, owes its origin to this process.

The first sweetener created from starch was the disaccharide maltose made in China about 1000 B.C. by the enzymatic hydrolysis of rice [3]. By 1781, it was known in Europe that starches could be treated with acids to produce a soluble, sweet-flavored substance [4]. This knowledge was little more than a laboratory curiosity until the Napoleonic Wars when the blockade of cane sugar imports from the West

Indies provided incentive for the development of alternative sweeteners.

In 1811, G. S. C. Kirchoff, who was looking for a substitute for gum arabic (used in the manufacture of porcelain), overcooked a mixture of potato starch and sulfuric acid [5]. The sweet, syrupy substance that resulted earned him a lifetime pension of 500 rubles per year from the Russian Emperor.

Kirchoff recognized the commercial potential of his discovery and proceeded to improve the process. He succeeded in preparing a syrup that crystallized partially on standing, and from which a solid product (impure D-glucose) could be obtained by pressing the mass in cloth sacks. This solid material contained large quantities of uncrystallized syrup and was quite impure. Nevertheless, serious attempts were made to manufacture the product on a large scale. However, the defeat of Napoleon at Waterloo made cane sugar available once again and the venture was abandoned.

The French chemist Saussure determined that the acid conversion of starch was achieved through a hydrolytic reaction that cleaved the linkages between the anhydroglucopyranose units in starch by adding one molecule of water to each unit to produce the basic building block, D-glucose. It was also recognized that candies manufactured with glucose syrups were not cloyingly sweet as were those made from sucrose, thus allowing delicate flavors to reach the palate. As a result, the "starch sugar" industry developed in Europe (especially in Germany) and in the United States [6].

Early efforts to improve the quality of "starch sugars" were attempts to control the nonspecific nature of the acid hydrolysis. The market needed purer glucose, but early commercial production (1880 – 1920) of crystalline glucose required either repeated crystallization steps or crystallization from nonaqueous solvents. The only solid form of glucose available in quantity at low price at this time was a cast product; starch was acid converted to as high a degree as possible, evaporated to a thick syrup, and poured into molds where it hardened into solid blocks. It was subsequently removed from the molds, chipped into small pieces, and sold.

In the United States in 1923, William B. Newkirk (Corn Products Refining Company) received a patent for developing a commercially feasible process for the production of pure crystalline glucose [7]. By careful control of the conditions during the crystallization step, large, easily separable crystals could be produced economically and an industry was born.

Although glucose and glucose-containing syrups can have functional advantages over sucrose (higher viscosity, greater solubility, bland flavor, etc.) in certain applications, the unmatched sweetness of sucrose prevented glucose-containing syrups from capturing more than about one-fifth of the caloric sweetener market in the United States. In many of its uses, sucrose in aqueous solution is treated with either acid or enzymes to produce invert syrup consisting of a 50 : 50 glucose – fructose mixture (→ Fructose). Thus, in a highly converted glucose syrup, isomerization of half of the glucose to fructose would make starch-based syrups about as sweet as those made from sucrose.

Glucose isomerization under alkaline conditions (see Section 2.3), which increases sweetness somewhat, results in a highly colored product with off-flavor. In 1957, a xylose isomerase enzyme was reported to convert glucose to fructose [8], and a US patent was issued to the Corn Products Refining Company in 1960 [9]. However, no industrial activity was immediately pursued in the United States, and glucose isomerase research shifted to Japan in the 1960s [10].

Once the economical enzymatic conversion of glucose to fructose had been demonstrated by the Japanese, the technology moved back to the United States. In 1965, the Clinton Corn Processing Company (United States) and the Japanese Agency of Industrial Science and Technology worked together to commercialize fructose-containing syrups made in the United States by enzymatic isomerization of glucose. At about the same time, the first batchwise production began in Japan.

The degree of enzymatic isomerization of glucose to fructose depends on a number of operating parameters. Because higher fructose content is desired, higher operating temperature and/or increased reaction time is required. However, both of these process conditions reduce the effective enzyme productivity. Although enzymatic isomerization of glucose to fructose in excess of 50 % db (dry basis) is possible, conversion to a 42 % db fructose content was chosen as the best balance between increased sweetness

and process economics. The first commercial shipment of 42 % fructose syrup in the United States was made in 1968.

This new sweetener began to replace sucrose in many liquid applications (see Table 1), but it was not sweet enough to satisfy the demands of the most important U.S. soft drink producers. By use of chromatographic separation techniques, the 42 % fructose syrup was enriched to a fructose content in excess of 90 % db. Blending this enriched syrup with 42 % fructose syrup, the sweetness level of total invert syrup was matched at 55 % fructose content. More than 50 % fructose was required because the various glucose polymers remaining in the syrup, due to incomplete starch hydrolysis have a lower sweetening power.

The first large-scale production of 55 % fructose syrup began in 1978; by 1984, fructose syrups derived from glucose had replaced sucrose in nearly 100 % of the soft drinks produced in the United States, substantially reducing sucrose consumption. Today, glucose-based sweeteners account for more than half of the total caloric sweeteners consumed in the United States (see Fig. 1) [12].

Figure 1. Per capita US sweetener consumption by type 1965 – 2005

North America, led by the United States, is the dominant leader in the production and consumption of glucose – fructose syrups, consuming 74.1 % of the world production of 11.8×10^6 t (dry basis) today, followed by Asia and Oceania at 14.8 %, with European consumers using 7.1 % and Latin America and Africa accounting for the remaining 4 % [13]. This market dominance is expected to continue for the forseeable future the major market growth (on a percentage basis) expected in Asia [14] has not occurred, because genetically modified organism (GMO) regulations have complicated maize procurement and low sugar prices have reduced substitution incentives [15]. Consumption of glucose – fructose syrups increased in the United States, on average, by 19 % annually between 1980 and 1985 and grew much faster than population (4 % annually) between 1990 and 1995. The per capita nutritive sweetener consumption in the United States peaked about 1999; since then, per capita consumption of glucose – fructose syrups has fallen about 1 % per year [16]. Imports of sugar-containing products may explain some of this reduction but reasons may also include reduced economic activity and a drop in the consumption of baked goods and cereal products in the United States [17].

Chromatographic enrichment to $> 90\,\%$ fructose syrups has allowed the economical production of crystalline fructose (→ Fructose) [18]. New drying and encapsulation technology claims to be able to produce solid glucose–fructose syrups [19], so that they can be used in certain dry applications as well.

2. Properties of Glucose

2.1. Structure

At the end of the 19th century, the general structure of glucose was elucidated by Emil Fischer. He found that the six carbon atoms of the glucose molecule are linked in a straight chain. At first glucose was thought to be an open polyhydroxy aldehyde. However, more than 99 % of the molecules exist as a six-membered cyclic hemiacetal which is formed by reaction of the aldehyde group with the hydroxy group at C 5. As a result, glucose does not undergo the specific addition reactions (e.g., with ammonia or sodium bisulfite) that are typical for aldehydes.

Glucose predominantly occurs in nature in the form of the D-enantiomer which is therefore important commercially. D-Glucose is generally believed to exist in three crystalline forms: anhydrous α and β-D-glucose crystals are both orthorhombic while α-D-glucose monohydrate crystals are monoclinic (see Fig. 2). However, a fourth form, thought to be a hydrated form of β-D-glucose, has been reported [22].

Conformation. In aqueous solution, D-glucose exists as a mixture of the α and β $^4C_1$ chair forms (approximately 62 % β and 38 % α when equilibrated at 31 °C [23]) that mutarotate from one anomeric form to the other through the open chain aldehyde form (see Fig. 3).

Chemical structure and conformation have been confirmed with the aid of high-field nuclear magnetic resonance spectrometry using superconducting magnets, advanced pulsars, and expanded computer capabilities to perform one and two-dimensional Fourier transform experiments [24].

* Rotation of an α/β equilibrium mixture = 52.7°.

2.2. Physical Properties

Some important physical properties of crystalline D-glucose are shown in Table 2. The large positive heat of solution of the crystalline monohydrate form imparts a unique cooling effect to the palate when incorporated into candy and icing in the crystalline state.

Solubility is an important property of glucose since it is crystallized commercially from aqueous solution and many of its commercial uses involve water systems. The solubility of glucose in water is shown in Figure 4 [25]. Below a temperature of ca. 100 °C, the stable, crystalline form of D-glucose is the α-form, which crystallizes as a monohydrate below ca. 50 °C; above ca. 100 °C, the β-anhydrous form is most stable.

2.3. Chemical Properties

Above a pH of 6.3, the open aldehyde form of glucose rearranges to keto-D-fructose (Lobry de Bruyn–van Ekenstein rearrangement → Carbohydrates, see Fig. 3).

Glucose is a *reducing sugar*, i.e., it reacts with oxidizing agents such as cupric hydroxide. Cupric hydroxide oxidizes reducing sugars more rapidly if the copper is kept in solution by the formation of a complex salt with tartrate ion (Fehling's solution) or citrate ion (Benedict's solution) to form red cuprous oxide. Benedict's solution is the more stable and is not affected by uric acid; hence it is preferred for detection of glucose in urine.

The inherent reducing property of glucose inhibits oxidative degradation in food; glucose maintains the bright red color of tomato catsup, red berry preserves, and red meats without the need for artificial antioxidants.

Glucose is fermented rapidly and completely by yeast and other organisms. The degree of fermentation possible (or fermentable extract) of glucose and glucose-bearing syrups is shown in Table 3.

Table 3. Fermentable extract values of glucose and glucose-containing syrups *

Substrate	Fermentable extract, wt % db
36 DE	34.8 [27]
42 DE	41.5 [27]
54 DE	53.4 [27]
62 DE	70.0 [27]
64 DE	76.0 [28]
68 DE	79.0 [28]
Glucose – fructose syrup	95.0 [27]
Crystalline glucose	100.0 [27]

* DE = dextrose equivalents; db = dry basis.

3. Raw Materials

Starch (→ Starch) is, for all practical purposes, the only raw material used for commercial pro-

duction of glucose-containing syrups today, although efforts have been made to utilize the other natural glucose polymer, cellulose, as well (→ Ethanol, Chap. 5.4.3).

All starches are polymers consisting of α-linked anhydroglucopyranose units (Fig. 5 A). Two types must be distinguished: Amylose (Fig. 5 B) is an essentially linear molecule in which the anhydroglucopyranose units are linked almost exclusively via α-1,4-bonds. Amylopectin (see Fig. 5 C) is a much larger, highly branched molecule (the molecular mass of amylopectin is ca. 1000 times that of amylose [29]); α-1,4 linkages predominate but there are a significant number of α-1,6-linkages which lead to branching. The proportion and structure of these fractions in starch granules vary, depending on the botanical source of the starch (Table 4). In general, amylose from grain sources has a lower degree of polymerization (DP), ranging from 200 to 1800, the DP of amylose from root or tuber sources is higher (ranging from 1000 to 6200). The amylopectin fractions have a much greater DP, averaging about 2×10^6 with no major difference between starch sources.

Maize has become the leading source of starch for conversion to sweeteners [34], although starch from barley, sago, sorghum, wheat, rice, potato, tapioca, and other starch-bearing grains and roots serves as the raw material for the production of glucose-containing syrups around the world. About 70 % of the world production of maize starch is converted to glucose-containing sweeteners; nearly 100 % of the glucose-based sweeteners produced in the United States and 84 % of the production in Japan are from maize. In Japan it is required by law that one part potato starch is used for every 12 parts corn starch for fructose syrup production. Although the use of wheat starch (as a co-product of vital gluten production) is increasing in Europe, glucose-containing sweeteners produced there also originate from maize starch. In Australia, however, all glucose-bearing syrups are produced from wheat starch.

In Asia, factories often use sago, tapioca, or maize (corn) starch for glucose production, depending on the availability and price of each ingredient. The starch source and purity have a strong influence on manufacturing requirements, but a variety of starches can be used successfully.

In Thailand, for example, a syrup called "Chinese Maltose" is produced from wheat and glutinous rice. In Pakistan, broken rice is used to produce 42 % fructose and enzyme – enzyme glucose syrups having qualities comparable to products made from maize starch.

4. General Principles of Starch Hydrolysis

Hydrolysis of starch occurs when linkages between the anhydroglucopyranose units are broken catalytically (by using either acid or enzymatic catalysts in the presence of heat) with the addition of water. The formation of the monomer (D-glucose) and of dimers having a 1,4-(maltose) or 1,6-(isomaltose) configuration are shown in Figure 6.

Mutarotation, (see Section 2.1), isomerization reactions (see Section 2.3), and possible repolymerization reactions, coupled with the complex chemical structures of amylose and amylopectin (which offer a number of possible hydrolysis sites), provide the potential for the creation of molecules having a nearly infinite number of combinations of ketohexose units (→ Carbohydrates).

A simplified flow diagram illustrating the process steps used to manufacture sweeteners from starch is shown in Figure 7. Starch hydrolysis is catalyzed by both acids and enzymes. Irrespective of the catalyst used, all processes begin with a water slurry of starch granules. After hydrolysis, insoluble protein, lipid material, and some of the inorganic components present initially in the starch are separated by either centrifugation or filtration (or both). The presence of free starch due to incomplete hydrolysis (detected by blue or purple hue with iodine staining) leads to difficult separation and must be avoided.

Additional impurities are removed by refining with activated carbon, decolorizing resins, or ion-exchange resins, either singly or in combination, before evaporation to final product solids concentration. Because color-forming bodies are ionic in nature and are efficiently removed by resins, the total demineralization of syrups, with or without carbon treatment, provides a product with improved color removal and color stability [83]. And, the removal of ionic material, notably chloride ions, reduces the corrosives tendencies

Figure 5. A) Anhydroglucopyranose unit. Shown as a 5-membered pyranose ring structure with each carbon identified by number
B) Linear molecular structure from Amylose; normally a molecule consists of 200 – 6200 units linked together with α-1,4 bonds
C) Amylopectin. Each "bead" represents an anhydroglucopyranose unit.
D) A branch point is detailed to show an α-1,6 bond

Figure 6. Hydrolysis of anhydroglucopyranose polymers

Table 4. Starch type, composition, and production [29 – 33]

Botanical starch source	Amylose content, wt % db *	Amylopectin content, wt % db *	World production, 10^6 t/a	Principal countries of production
Arrowroot	20	80		Brazil, China
Barley	19 – 23	77 – 81		Europe
Maize				
Normal	26 – 28	72 – 74	27.6	United States, Japan, Europe, former states of USSR
Waxy	0 – 2	98 – 100		United States
High-amylose	55 – 85	15 – 45		United States, Australia
Potato	20 – 24	76 – 80	2.7	The Netherlands, Japan, Poland, former states of USSR
Rice	14 – 26	74 – 86		Asia, South America
Sago	27	73	< 0.1	Indonesia, South America
Sorghum	22 – 27	73 – 78		Asia, United States

Wheat	19 – 27	73 – 81	2.92	Australia, Europe, United States

* db = dry basis

of syrups allowing the use of less expensive materials of construction in process equipment located after ion exchange.

Glucose-containing syrups are generally categorized by their degree of conversion as measured by the amount of reducing sugars present. Although it is becoming more common for customers to specify a range of saccharide distribution to obtain desired functionality, glucose syrups can be divided into groups on the basis of their *dextrose equivalent* (DE) as shown in Table 5.

Table 5. Classification of glucose-containing syrups according to dextrose equivalents (DE)

Degree of hydrolysis	Accepted terminology
< 20 DE	maltodextrins
20 – 38 DE	type I syrup
38 – 58 DE	type II syrup
58 – 73 DE	type III syrup
≥ 73 DE	type IV syrup

Most glucose-bearing syrups are sold in liquid form usually containing between 70 and 85 % dry substance, but they can also be dried to form granular, semicrystalline, or amorphous products. These "solid syrups" range in degree of conversion from low-DE maltodextrins to highly converted (> 96 % DE) "total sugars" [84].

4.1. Production and Properties of Acid Glucose Syrups

In the acid conversion process, a starch slurry usually having a dry substance content between 30 and 40 wt % is acidified to pH 2 or lower and subjected to a combination of time, temperature, and pressure to effect hydrolysis. Higher temperature, permitted by operation under pressure, reduces the reaction time considerably. KIRCHOFF's conversion at atmospheric pressure, for example, lasted 36 h, early starch converters that were limited to pressures of 35 kPa took 6 h to complete the reaction. At 415 – 620 kPa and up to 160 °C, modern converters accomplish the conversion within minutes. Acid conversion can be accomplished by using either batch or continuous equipment although continuous conversion is used almost universally today.

When the desired degree of conversion is achieved, temperature and pressure are reduced and the reaction is stopped by addition of a neutralizing agent (usually sodium carbonate), raising the pH to 4 – 5.5. Insoluble compounds are then removed, and the syrup is refined and evaporated to the desired final concentration.

While acid conversion is a random-action mechanism, it results in remarkably reproducible saccharide composition for any given degree of hydrolysis. Typical compositions of acid glucose syrups are shown in Table 6. This reproducible composition is actually a limitation of the acid process because the manufacturer

Figure 7. Simplified process flow for the production of sweeteners from starch
* HFS = High-fructose syrup

Table 6. Saccharide composition of acid-hydrolyzed glucose syrups

Degree of polymerization	Dextrose equivalent (DE) of glucose syrup			
	27 – 30	34 – 36	42 – 43	55
DP 1 (glucose)	9 – 10	13 – 14	19 – 20	31
DP 2 (maltose)	8 – 9	11 – 12	14	18
DP 3 (maltotriose)	9 – 10	10	12	12 – 13
DP 4 (maltotetrose)	7 – 8	8 – 9	9 – 10	10
DP 5 (maltopentose)	7	8	8	7
DP 6 (maltohexose)	6	6 – 7	7	5
DP 7 (higher sugars)	50 – 54	40 – 42	29 – 31	16 – 17

cannot influence the saccharide distribution for a given degree of conversion, which is important in some applications of glucose syrups.

Additionally, acid syrups having a DE value below ca. 30 will tend to cloud upon standing due to precipitation (retrogradation) of the longest chain linear polymers. Also, although acid hydrolysis to DE values in the high 80s is possible, the extreme conditions required to produce DE values greater than ca. 55 pro-

mote the formation of excessive amounts of glucose degradation products (e.g., 5-hydroxymethylfurfural see Section 2.3) which are difficult to remove during refining. These color precursors cause the product to yellow eventually. The most common acid glucose product has a DE value of about 40 – 45 % because of these upper and lower conversion limitations.

The limitations at both the low and the high ends of the conversion spectrum, coupled with the inflexible saccharide distribution resulting from acid hydrolysis, led manufacturers to investigate enzymatic hydrolysis as a means of making improved glucose-containing syrups.

4.2. Production and Properties of Acid – Enzyme Glucose Syrups

Coupling a secondary enzymatic hydrolysis to a preliminary acid cleavage allows expansion of the range of DE values both up and down. It also permits control over the saccharide distribution by enzyme selection.

After acid hydrolysis, the temperature is lowered and the pH is raised to levels compatible with the enzyme to be used; a pH between 4 and 6, and a temperature in the range of 60 – 70 °C are usually employed. Additionally, the degree of acid hydrolysis is usually (but not always) lower when making acid-enzyme syrups (see also → Enzymes, Chap. 5.1.3.2).

If the goal is a high glucose content, control of the acid hydrolysis step to produce a DE of 10 – 20 is important. Higher DE levels result in reduced glucose yield during subsequent enzymatic hydrolysis due to the presence of acid-polymerization products that resist enzymatic conversion; conversely, starch retrogradation can occur with a DE less than 10, resulting in problems during clarification.

If maximum glucose content is not the aim, a higher DE value is usually chosen and the syrup can be clarified immediately after acid hydrolysis or the insoluble substances can be allowed to remain during enzymatic conversion.

If the insoluble compounds are removed, the acid hydrolysate can be enzymatically converted continuously, by using immobilized enzymes; otherwise, a batch treatment (with single use of the enzymes) must be employed.

When the desired level of enzymatic conversion is achieved by *batch conversion*, residual enzymes are deactivated with heat or pH adjustment, or are removed by refining. With *immobilized enzyme treatment*, the degree of conversion is controlled by the flow rate through a bed of insoluble enzymes; because the enzymes remain in the converter, their removal from the syrup is unnecessary. Refining and evaporation follow as in acid glucose syrup manufacture.

Bacterial *α-amylases* (E.C. 3.2.1.1) [*9000-90-2*] cleave α-1,4-linkages in a random fashion whereas *β-amylases* (E.C. 3.2.1.2) [*9000-91-3*] (and to a lesser degree, fungal α-amylases) mainly produce maltose, again only cleaving α-1,4-linkages. *Glucoamylase* (E.C. 3.2.1.3) [*9032-08-0*], on the other hand, splits off one glucose molecule at a time from the non-reducing end of the polymer by hydrolyzing α-1,4-linkages; glucoamylase also has the capability of splitting α-1,6 linkages but at a much slower rate. *Pullulanase* (E.C. 3.2.1.41) [*9075-68-7*] can split α-1,6-linkages, and addition of this enzyme in combination with another enzyme(s) increases the capability of tailoring saccharide distributions [30].

At first, enzyme conversion was used to extend the degree of conversion upward, primarily to maximize glucose production for the manufacture of crystalline glucose as well as for the production of sweeter, less viscous glucose-containing syrups. However, it also enabled selective production of either more maltose or more glucose, depending upon the enzyme chosen. This is illustrated by the compositional data shown in Table 7.

4.3. Production and Properties of Enzyme – Enzyme Glucose Syrups

The development of α-amylase from bacterial sources capable of withstanding the high temperature needed to gelatinize starch completely allowed the development of totally enzymatic processes that further expanded control of saccharide range and distribution. A total enzymatic conversion process eliminates the need for preliminary acid hydrolysis.

Thermostable α-amylases are added to a starch slurry (containing calcium as an enzyme stabilizer) that has been adjusted to a pH of

Table 7. Saccharide composition of various acid – enzyme glucose syrups

	High maltose			High glucose	
DE	DE 42 – 43	DE 48 – 50	DE 60 – 63	DE 70	DE 95
DP1 (glucose)	6 – 8 %	9 – 10 %	31 – 36 %	43 – 47 %	92 %

DP6 (maltohexose)	2 %	2 %		2 – 3 %	
DP7+ (higher polymers)	26 – 30 %	18 – 20 %		9 – 10 %	

DP = Degree of polymerization.

6 – 6.5. A pH lower than 6.3 is preferable to prevent the formation of maltulose (4–*O*-α-D-glucopyranosyl-D-fructose) [35]. Maltulose cannot be converted enzymatically to glucose and its formation reduces glucose yield.

The recent introduction of a novel α-amylase capable of liquefying starch at pH 4.5 without the need for calcium ion addition has the potential to reduce chemical and refining costs as well as possibly eliminate the formation of maltulose. This enzyme's action pattern reportedly can increase the production of saccharides with low DP (1 – 4) while practically eliminating the higher saccharides (DP 8+). This characteristic allows higher solids levels during liquefaction [36]. While presently employed for the manufacture of ethanol from starch and whole grains, the application in the manufacture of starch sugars holds interest.

The slurry is heated, usually by direct steam injection, to ca. 103 – 107 °C and held for 5 – 10 min to liquefy the starch completely. A subsequent holding period of 1 – 2 h at about 95 °C allows continued enzymatic activity to raise the DE to a value between 10 and 15. The temperature and pH are then adjusted to levels compatible with the enzyme used for the secondary conversion. From this point, the process is similar to the acid – enzyme process.

On the high end of the glucose conversion scale, a totally enzymatic conversion greatly increases the yield of glucose while decreasing the refining requirements. The composition of highly converted syrups produced by acid, acid – enzyme, and totally enzymatic hydrolysis with respect to glucose concentration and impurity content is shown in Table 8.

Maximum glucose content during glucoamylase saccharification is also determined by solids content in the slurry; at 30 wt %, a glucose level of 96 wt % db is usually achieved. Decreasing the solids content to 10 – 12 wt % allows glucose levels of 98 – 99 wt % db to be reached. This higher glucose yield is produced at the expense of increased evaporation cost and risk of microbial contamination, and is seldom used commercially because chromatographic separation technology has become available and allows the increase of the glucose content of syrups to be $>$ 99 wt % db. Nanofiltration has also been used to enrich glucose content [37].

Total enzymatic conversion also affects the characteristics (via saccharide distribution) of less highly converted glucose-bearing syrups, as shown in Table 9. Syrup viscosity is an important property that can be affected by shifting saccharide distribution.

The viscosity is increased mainly by the longer chain polysaccharides. Thus, at a constant DE value, solids content, and temperature, an acid-hydrolyzed syrup would have the highest viscosity, an acid – enzyme syrup would be intermediate, and an enzyme – enzyme syrup would have the lowest viscosity. Viscosity affects the handling and storage temperature as well as the application properties. Many desirable results occur from lowering the viscosity, including improved flavor release in sweets, lowering of boiling temperature in candy manufacture, faster operation of candy production lines, and better "set" in jellies and jams.

Enzymatic conversion also allows the production of syrups with reduced glucose content. In the presence of protein, glucose undergoes non-enzymatic browning due to the Maillard reaction more readily than polymers of glucose. Syrups with higher concentrations of glucose polymers are more color stable.

Table 8. Effect of conversion method on composition of filtered unrefined highly converted glucose-containing syrup

	Conversion method

DP 7+	30	30	23.7

5. Production of Solid Glucose

Whereas most glucose is sold as glucose-containing syrups, a portion is sold as granular free-flowing solids. In this form it can be incorporated into dry mix products and shipped without the added cost of transporting water. Bagged product accommodates smaller-scale users. Solid products include total sugars and pure crystalline forms of glucose (dextrose). Total sugars are solidified hydrolysates that can either be in glassy (amorphous) or crystalline states. Pure glucose crystals are grown from aqueous solution to form a slurry of pure crystals in mother liquor (massecuite), the crystals are separated from the mother liquor by centrifugation and dried in hot air dryers.

5.1. Production of Total Sugars

When the entire starch hydrolysate is solidified, it is called a total sugar. A variety of processes have been developed to produce total sugars [84]. Dry maltodextrins have a DE of less than 20 while corn syrup solids have higher DE values, commonly between 24 and 48. Highly converted total sugars usually contain between 95 and 99 % db glucose although processes have been patented for the production of fructose-bearing total sugars and solid starch sugars that incorporate other ingredients such as intense sweeteners.

About 40 % of the crystalline glucose sold in Japan is a solidified hydrolysate (*total sugar* form) of monohydrate glucose distantly related to the cast product produced early this century (but of much higher purity due to enzymatic starch hydrolysis, modern refining methods, and evaporation under high vacuum).

More than half of the crystalline glucose sold in Korea is also a monohydrate total sugar that is used as a carrier in many dry foods. These total sugars are produced by using a modern, continuous solidification process that employs spray drying of a partially crystallized, refined hydrolysate [38, 39].

However, with the exception of a relatively small amount of spray-dried hydrolysate products (a monohydrate product with the trade name Cantab produced by Penford Products Products Co., United States and an anhydrous product manufactured by Cargill, United Kingdom/United States), total sugars have not been the large market successes in the West that they have in the Orient; in Europe and the Americas, pure glucose crystals (in either the monohydrate or the anhydrous form) are the more universally accepted product.

5.2. Production of Pure Crystalline Products

Initially, crystalline glucose was produced from acid-converted starch hydrolysates. Because of degradation products formed during conversion,

the maximum glucose content achievable in the hydrolysate was limited to about 88 % db. By 1938, enzymatic conversion processes were being developed that provided much purer sources from which crystalline glucose could be manufactured.

Either continuous or batch crystallization can be used to produce the desired crystals. In *continuous crystallization*, supply liquor is either mixed with recycled seed crystals or new crystals are formed by spontaneous nucleation. In *batch crystallization*, a portion (usually 15 – 30 %) of the finished batch is retained in the crystallizer and mixed with the supply liquor.

Supersaturation to promote crystal growth can be achieved by either cooling or evaporation [40, 41]. When continuous crystallization is employed for the production of monohydrate dextrose crystals that form below 50 °C, great care must be taken to prevent microorganisms, primarily yeast, from acting on the glucose solution. Yeast fermentation is only a problem at the lower temperature and solids levels, that occur at high crystal content at the final crystallization conditions.

When producing glucose monohydrate, batch crystallization has the advantage that the operating conditions at the beginning of the cycle (highest temperatures and solids content) are hostile to yeast. Thus, when hot supply liquor is mixed with a portion of the previous batch, any yeasts that might be present are killed.

Because a conventional batch crystallizer process retains a portion of the finished product to be mixed with supply liquor for the next batch, a more efficient process for the production of glucose monohydrate has been proposed [42]. By continuously producing a lean phase massecuite in a continuous crystallizer, that is operated at temperature and solids level hostile to yeast, and then supplying this material to a batch crystallizer to produce a high-crystal-content massecuite suitable for centrifuging, the full operating volume of the batch crystallizer is used for production; the batch crystallizer is completely emptied at the end of the crystallization cycle, and the processing time devoted to seed mixing is eliminated.

Since anhydrous glucose crystals form above 50 °C, yeast fermentation is not an issue and either batch or continuous crystallization can be used.

Production of Glucose Monohydrate Crystals. The α-D-glucose monohydrate crystals, usually produced by batch crystallization, have the largest share of the world market. Starting material for the manufacture of glucose crystals is a syrup with a glucose content of 95 – 96 wt % db produced by enzymatic hydrolysis of starch to the highest practical degree. This syrup is produced and refined by using the process described previously for the production of enzyme – enzyme glucose syrups.

In a typical batch crystallization process, the syrup is evaporated to a solids content of 74 – 79 wt %. Higher solids content results in increased crystallizer productivity [43]. The supply is cooled to about 46 – 50 °C, and mixed with seed crystals (left behind from the previous batch) in crystallizers (see Fig. 8). As mentioned previously, an alternative process having greater productivity would utilize continuous crystallization to produce a lean massecuite that would be supplied to the batch crystallizer, thus allowing complete emptying of the batch unit at the end of the cycle. Alternatively, continuous crystallization could be used entirely.

Figure 8. Batch monohydrate glucose crystallizer

B) External side view a) Supply liquor inlet; b) Inspection hatch; c) Bearing; d) Cooling water connections; e) Support saddle; f) Massecuite discharge valve

The resulting mixture is cooled slowly, usually by indirect heat transfer to a final temperature between 20 and 40 °C over 2 – 5 d during which about 60 % of the glucose is crystallized in the α-monohydrate form, yielding a viscous

magma of crystals and mother liquor. Exact values of the solids concentration, the initial and final temperatures and the rate of cooling depend on the glucose content of the crystallizer supply [44 – 46].

The resulting magma is routed to perforated screen centrifuges (usually batch machines) to separate most of the mother liquor from the crystals; most of the remaining mother liquor is then removed by washing the crystals with a spray of water.

The crystals are spun as dry as possible (about 14 wt % moisture content) and then transferred to continuous rotary dryers (→ Drying of Solid Materials) where they are dried in a stream of warm, filtered air to 8.5 – 9.0 wt % moisture content, slightly below the theoretical moisture content of the monohydrate (9.08 wt %).

Because crystallization of glucose monohydrate occurs satisfactorily despite the presence of large quantities of impurities [4, 47], the mother liquor can be reconcentrated and a second crop of crystals can be recovered. The presence of impurities alters the crystal size and shape; purer liquors produce longer, narrower crystals than those produced from less pure solutions [48].

Otherwise, a portion of the mother liquor can be recycled and combined with the incoming hydrolysate as supply to a single crystallization step. Either process increases the yield of glucose crystals from a given amount of hydrolysate. Recovery of as much as 87.5 % of the glucose from the incoming hydrolysate as monohydrate crystals has been reported [49]. By reconverting the mother liquor, yields approaching 100 % have been reported [85].

Production of Anhydrous Crystalline Glucose. Anhydrous crystalline glucose is produced in evaporative crystallizers operated in either a batch or a continuous mode. *Anhydrous* α-D-*glucose* is usually produced in batch vacuum pan evaporative crystallizers operated at 60 – 65 °C. The crystallization cycles are much shorter than those needed for monohydrate production, usually only 6 – 8 h [4]. The crystals are separated from the mother liquor, washed, and dried in a manner similar to monohydrate crystals, but the final product moisture is less than 0.1 wt %.

Production of anhydrous glucose crystals is more demanding than that of their monohydrate relatives and they can only be successfully crystallized from relatively pure solutions [4]. The purest grades (U.S.P.) are produced from very pure glucose syrups made by dissolving monohydrate glucose crystals in water.

Anhydrous β-D-*glucose* can be produced by operating the crystallization step slightly above 100 °C [4]. Another commercial method of preparing a crystalline glucose total sugar rich in the β-anomer consists of spraying a hot, concentrated glucose syrup onto a moving bed of previously made product at high temperatures (85 – 105 °C) in a rotary dryer to yield a granular, pearl-shaped crystal [50].

The β-anhydrous glucose is much more soluble than the α-form (72 wt % vs. 30 wt % at 25 °C, the solubility of the equilibrium α-β-mixture is 51 wt % at 25 °C).

6. Glucose – Fructose Syrups

6.1. Properties

Isomerization of glucose to fructose significantly increases the sweetness of starch-based sweeteners. This single property propelled the market share of starch sweeteners from 20 to over 50 % in the United States. More than half of the starch-based sweeteners sold in Japan and about two-thirds of those sold in the United States are 42 and 55 % fructose syrups.

Sweetening Power. Sweetening power cannot be measured quantitatively in absolute terms but can be determined subjectively by using trained taste panels. Many factors including stereochemical configuration influence the perception of sweetness: α-glucose is definitely sweeter than the β-form [51]. Stereochemistry can explain the wide variation in reported sweetness of fructose, whose crystalline form β-D-fructopyranose undergoes rapid tautomerization in solution to five forms: α and β-D-fructopyranose as well as α and β-D-fructofuranose and open chained keto-D-fructose. Thus, although crystalline fructose is reportedly 1.8 times as sweet as sucrose, solutions of fructose are much less sweet than crystalline fructose because of the tautomeric distribution in water [52].

Figure 9. The relative sweetness of glucose-containing and fructose – glucose syrups vs. composition
All data at about 10 wt % solids water solutions, except [54] □ [55]; ● [56]; ○ [51]; ▲ [54]; ▼ [53]; ■ [57]; + [58]; △ [59]; ▽ [60]; ♦ [61];

Concentration [51], temperature, and pH [53] affect the perception of sweetness too. To eliminate the possibility of enzymatic hydrolysis in the taster's mouth, rapid and consistent evaluation procedures are required, especially when tasting low-DE syrups.

In general terms, however, as the glucose content of glucose-containing syrups increases, sweetness increases; as glucose is isomerized to fructose, sweetness increases further. The sweetness of glucose-containing syrups, relative to sucrose, in solutions of about 10 wt % solids concentration is shown in Figure 9.

Most glucose–fructose syrups are usually produced from enzymatically converted high glucose (95 – 96 % db) hydrolysates which are the fructose–glucose syrups shown in Figure 9. However, lower DE syrups that have been isomerized slightly to 10 wt % fructose content to increase sweetness are sold in the European Union. Syrups isomerized to this low level do not violate fructose production quotas that have been established to protect domestic sucrose production.

Chemical Properties. Fructose reacts with amino groups (Maillard reaction) much more readily than glucose does (→ Fructose) [62]. Therefore, glucose – fructose syrups must be refined to a greater degree and are inherently less stable. Fortunately the higher water solubility of fructose (→ Fructose) allows lower storage temperatures without crystallization (see Chap. 9).

6.2. Production

The clarified, refined, and ion-exchanged high-glucose-content syrup is evaporated to a 40 – 50 wt % solids level. Magnesium(II) ions (usually as $MgSO_4$) are added as a cofactor to activate and stabilize the isomerase enzyme, as well as to overcome the inhibitory effect of residual calcium not removed by ion exchange.

This feedstock is then passed through reactors containing immobilized glucose isomerase (E.C. 5.3.1.18). Process conditions vary depending upon the supplier of the enzyme but most systems operate at 55 – 65 °C and with pH of 7.5 – 8.5. The flow rate is adjusted to yield a product having a minimum of 42 % of the dry substance converted to fructose.

Enzymatic activity decreases during the effective life of the reactors due to thermal inactivation and the presence of trace impurities in the feed liquor. Fructose content is maintained at the desired 42 % level by reducing the flow rate through the columns. The effective life of

a reactor is several months; during this period, the nominal retention time in the reactor may increase typically from 0.5 to as much as 4 h.

Immediately after isomerization, the pH is lowered to 4 – 5, the syrup is refined and evaporated to the final concentration.

Chromatographic Enrichment. Although 42 % db fructose syrups are nearly as sweet as sucrose, the fructose content had to be increased to 55 % db to provide the exact sweetness match demanded by the soft-drink market. This is accomplished by employing chromatographic separation techniques to separate 42 % fructose syrups into fructose-enriched and glucose-enriched streams.

Separation is accomplished by passing the 42 % fructose syrup through an adsorbent resin containing calcium ions. Fructose is bound to the adsorbent to a greater extent than glucose (and polymers of glucose). Elution with water produces a discharge stream initially rich in the loosely bound glucose and glucose polymer fraction, followed by a fraction rich in the more tightly bound fructose. A continuous (simulated moving bed) process is used commercially, in which 42 % fructose supply liquor and elution water enter the columns at different points, while glucose-rich and fructose-rich product streams are withdrawn at others. The points of addition and withdrawal are moved along the bed periodically to correspond to changes in composition within the column [63, 64].

Typical operation uses 50 wt % solids feedstock (42 % fructose). The separation produces a glucose- and glucose-polymer-rich byproduct stream that is recycled either to the isomerization step (to convert additional glucose to fructose) or back to the hydrolysis step (to convert the glucose polymers to glucose). A fructose-rich stream containing 80 – 95 % db fructose is the primary product (the composition depends on the equipment and operating conditions). This fructose-rich stream is blended with 42 % fructose syrup to produce a 55 % fructose syrup that is refined and evaporated to the final concentration.

The fructose-rich stream can also be refined and evaporated to about 80 wt % solids for customers requiring a very high fructose-content product. At the highest fructose levels, it can supply a crystallization process to produce fructose crystals.

In 1987 more than 80 commercial factories on almost every continent were reported to produce more than 6.6×10^6 t (dry basis) per year of glucose–fructose syrups [65]. Worldwide production increased to 10.1×10^6 t (dry basis) per year in 1995 and is estimated to have grown to nearly 12.5×10^6 t (dry basis) in 2002 before dropping to 11.8×10^6 t (dry basis) per year in 2005 [14]. The phenomenal growth of glucose – fructose syrup (called high fructose corn syrup or HFCS in the United States) production is shown in Figure 10.

Figure 10. Growth of glucose – fructose syrup production, 1968 – 2005

6.3. High-Fructose Syrups from Inulin

Inulin is a naturally occurring polymer of fructose which replaces starch as the food reserve in many plants of the family Compositae (e.g., Jerusalem artichoke, chicory, salsify, cardoon elecampane, burdock, dahlia, and ti plants).

Figure 11. Part of an inulin chain

The mature inulin molecule has an M_r of 3000 – 5000 and consists of 17 – 30 anhydrofructose units and a terminal glucose unit (see Fig. 11). The chain length varies during the growing season, and consequently, the glucose – fructose ratio is not constant [66].

A process for the production of high-purity fructose syrup from inulin-containing roots has been described [67]. The pH of extracts is raised to > 11 using lime, to precipitate impurities. Under these conditions, inulin is not precipitated by high levels of calcium (as is fructose) and can be recovered by filtration [68].

The lack of commercial interest in high-fructose syrup production from inulin is probably due to the high quality of fructose syrups produced by isomerization of glucose followed by chromatographic separation, and to lack of the large crop production industry needed to produce inulin. While the Jerusalem artichoke is reported to produce tuber yields as high as 100t/ha [86], present commercial sources of inulin are primarily obtained from chicory [87]. While some fructose is being produced, much of the inulin is partially enzymatically hydrolyzed to make a range of nondigestible oligofructose ingredients that are finding use as fat mimetics. Only the European Union is a substantial producer of fructose-containing inulin syrup that originally was not limited by production controls as was glucose-derived fructose syrups. Inulin syrups have now been brought under control by the EU.

7. Analysis

Solids concentration of glucose-containing syrups is usually measured by refractive index or density. This measurement can be related to dry substance or the more traditional Baumé or specific gravity values by using established mathematical models and conversion factors that compensate for syrup composition. Glucose-containing syrups are sold at concentrations usually varying between 75 and 85 wt % solids. Glucose–fructose syrups are usually produced at 71 – 75 wt % solids for the 42 % fructose syrup and 75 – 77 wt % solids for the 55 % fructose product. The moisture content of dry products (crystalline glucose and solid glucose

syrups) is usually measured by weight loss under vacuum drying or by Karl Fischer titration.

The *carbohydrate composition* of glucose and glucose–fructose syrups is almost always measured by high performance liquid chromatography (HPLC). The carbohydrate composition can be related to the traditional dextrose equivalent (DE) by calculation [69]. However, direct measurement is still practiced by using copper reduction (the Lane and Eynon method) [70].

The *color of syrups* is generally measured by the amount of light transmitted through (or absorbed by) a fixed depth of syrup. The wavelength of the light beam is chosen to be most sensitive to soluble impurities such as ash. Most syrups are referred to as "water white"; their color content is so low that it is difficult to distinguish (visually) between syrups and water.

8. Legal Aspects

The legal aspects of glucose-containing products are governed by a number of regulations defined, in part, by such references as the U.S. Code of Federal Regulations, the Codex Alimentarius Commission, and the U.S. and British Pharmacopeia. In the United States, glucose syrups and monohydrate and anhydrous crystalline glucose are considered standardized foods by the U.S. Food and Drug Administration, while fructose syrups derived from glucose are considered as GRAS (generally regarded as safe) with specifications defined by the Food Chemicals Codex of the National Academy of Sciences.

Solid Concentration. The Codex Alimentarius Commission recommends that the solids content of *glucose-containing syrups* be no less than 70 wt %. The U.S. Code of Federal Regulations (CFR) specifies that *anhydrous crystalline glucose* contain no less than 98 wt % dry substance (in practice, the commercial product usually contains < 0.1 wt % water) and that *monohydrate crystalline glucose* contain no less than 90 wt % dry substance (in commercial practice, dry substance ranges between 91 and 92 wt %).

Carbohydrate Composition. The Codex Alimentarius recommends that glucose syrups have a DE value not lower than 20 (below this level they are defined as maltodextrins). The CFR requires that *crystalline glucose* have a DE value no less than 99.5 [66].

Impurity Content. Ash content limits of 1 wt % for *syrups* (Codex Alimentarius) and 0.25 wt % for *food-grade crystalline glucose* (CFR) are met easily by modern ion-exchange refining. The U.S. Pharmacopeia places much stricter specifications (including specific rotation, acidity, residue after ignition, and content of chloride, sulfate, arsenic or other heavy metals, and other components) on pharmaceutical-grade glucose [72].

9. Storage and Transportation

Storage temperatures of glucose-containing syrups are a compromise between low temperatures to minimize color development with time (see Fig. 12) and high temperatures either to reduce the viscosity of low-DE syrups below 15.0 Pa s (to allow handling with lobe or vane pumps) or to prevent crystallization of glucose in higher DE syrups. Suggested temperatures for various syrups are shown in Table 10.

Figure 12. Glucose-containing syrup color as a function of time and temperature
a) 54 °C; b) 49 °C; c) 38 °C; d) 27 °C

Shipping containers for syrups range in size from 200 L drums to jumbo railcars holding 90 t.

Table 10. Storage conditions of glucose-containing syrups

Syrup type	Solids content, wt %	Temperature, °C	Limiting condition
42 DE	80	38	viscosity
	83	49	viscosity
60 DE	82	32	viscosity
	84	41	viscosity
95 DE	71	49	crystallization
42 HFCS	71	32	crystallization
55 HFCS	77	27	crystallization
90 HFCS	80	16	crystallization
Liquid glucose (99.5 DE)	71	52	crystallization

Trucks carrying 25 t are also used. Alternatives to drums include 1000 L disposable containers consisting of reinforced corrugated board outer containers holding a heavy-duty plastic bag.

Bags for storage of *crystalline glucose* and *solid syrups* must be protected against atmospheric moisture pickup by incorporation of a vapor barrier in the bag construction. Storage temperatures of solid products should be lower than 40 °C and rapid temperature changes should be avoided to minimize product caking.

Crystalline glucose is shipped in vapor-resistant bags usually containing 50 or 100 pounds (or the approximate metric equivalent sizes of 20, 25, and 40 kg) and in bulk trucks and railcars (jumbo railcars can hold as much as 82 t). Reusable containers holding about 1 t of crystalline material are used for customers who do not require bulk delivery and who do not want the bother and expense of bag opening and disposal.

10. Uses

Glucose-containing syrups and glucose are used in a variety of food and nonfood applications. The manufacturing flexibility provided by enzymatic conversion techniques, coupled with modern refining and concentrating technology, provides a wide range of properties useful to the food formulator. Table 1 illustrates the relative volumes of usage in major food industries in the United States. The impact of the introduction of glucose–fructose syrups on other glucose applications can also be seen from this table. The rapid and complete fermentation of glucose is a valuable property in the fermentation and baking industries. In countries where its use is permitted by law, glucose is used by the brewing industry. Glucose also serves as a raw material for the manufacture of food-grade acids (citric, lactic, acetic, etc.), enzymes, amino acids, vitamin C, and a variety of antibiotics.

The largest nonfood use of unrefined glucose-containing syrups is as a carbohydrate source for the production of fuel-grade ethanol (→ Ethanol, Chap. 5.1.2). In 1986, the annual production capability in the United States was reported to be ca. 2.7×10^9 L [73] and a 1988 article indicated a capacity of 3.9×10^9 L annually [74]. Annual U.S. production capacity in 2006 was reported as 1.68×10^{10} L [75]

In other applications, the dehydration of glucose to 5-hydroxymethylfurfural allows the incorporation of glucose-containing syrups into phenolic and urea – formaldehyde-based plastics [76]. Heating glucose and methanol in the presence of anhydrous hydrogen chloride yields α-methyl-D-glucoside which is used for insulating foams. Catalytic hydrogenation of glucose yields sorbitol.

Glucose-bearing syrups are also added to adhesives to improve stability and flow control, used as humectant in wallboard and tobacco manufacture, added to tiles and bricks to prevent cracking during manufacture, used to retard setting in concrete, are applied in resin and dye manufacture and leather tanning to name but a few of their nonfood uses.

11. Economic Aspects

The economics of starch-based sweeteners are related to the economics of sucrose (cane and beet sugar) except for uses in which production costs and unique functionality allow higher prices (such as high-purity crystalline glucose for intravenous injection) or significant competition causes price reduction (such as glucose syrups in the United States). In countries where

no protective tariff exists and sucrose is sold essentially at world prices, the domestic consumption volume of starch-based sweeteners depends on sucrose pricing. For non tariff nations, consumption and pricing figures can vary significantly from year to year. The production and pricing of starch-based sweeteners around the world are shown in Table 11.

Raw material (starch) pricing is also an important factor. Competition of markets for starch-based products, primarily used for the production of high-fructose syrups and fermentation to fuel-grade ethanol has become important in recent years. The impact of these two products on the growth of the corn wet milling industry in the United States is shown in Figure 13. In 2004, corn (maize) consumption for ethanol production amounted to more than half of that consumed by all food and industrial uses in the United States. While the food and industrial use of maize in the United States has grown substantially since the 1970s, farm production has more than kept up. The price of maize during this period has trended downward (see Fig. 14).

Figure 13. Growth of corn wet miller's shipments in the United States 1929-2005, comprising starch, refinery products, fuel ethanol and coproducts

Figure 14. Average annual corn and net corn price 1 bushel corn = 25.4 kg

But the real cost of maize to starch-based sweetener manufacturers is the cost of maize (corn) minus the income from the sale of coproducts of the wet milling process (corn gluten feed, corn gluten meal, and corn oil), i.e., the net corn cost. Year-to-year, net corn cost has followed corn price in the USA since the 1970s but the trendlines for corn and net corn cost are converging, indicating an average reduction in coproduct credit of 37 cents per bushel over the past 30 years (see Fig. 14.). The rapid growth in starch use in non-sweetener applications and the impact on raw material cost and the price of glucose-bearing products has been analyzed [77, 78]. To date, it appears that agricultural productivity increases have more than kept up with expanding food and industrial use of maize in the United States, keeping maize cost stable. For wet millers in the USA, increased volumes of coproduct have negatively impacted their prices, primarily for corn oil and corn gluten feed. Since fuel ethanol production is expected to nearly double by 2012, net corn cost must be watched.

12. Physiological Properties and Toxicology of Glucose

Glucose is absorbed into the bloodstream and used by the body (via the glycolytic cycle) for energy production or converted into other metabolic intermediates required for growth or maintenance of body tissues. By polymerization into glycogen (a highly branched macromolecule referred to as body starch), it is also stored in the liver for future use.

Glucose (and other sugars) acts as a dietary chelating agent under certain conditions, binding iron and several other di- and trivalent metals [79]. Simultaneous ingestion of glucose and a calcium supplement is reported to boost the body's uptake of that mineral by 25 % [80]. Blood serum cholesterol and phospholipid levels are reportedly lowered within days of beginning a high-glucose, lipid-free diet, whereas single doses of glucose syrup may be responsible for improved intellectual performance [81].

The lethal dose of glucose has been reported as 20 g/kg of body weight when administered orally to rabbits (the lethal intravenous dose for the rabbit is 15 – 35 g/kg). The lethal oral dose for dogs is ca. 8 – 12 g/kg [82].

Table 11. Production and pricing of starch-based sweeteners by country (all production values in 10^3 t of dry substance per year, 1996 values used except where noted.)

Country	Glucose syrups	Maltose syrups	Crystalline glucose		Total sugar	Fructose-glucose syrup

Abstract

Glycerol is the simplest triol. It can be found in all natural fats and oils as fatty esters and is an important intermediate in the metabolism of living organisms. It is completely miscible with water and many alcohols and also with many heterocyclic compounds. A remarkable and growing source of glycerol is as a byproduct in the production of biodiesel. Glycerol is presently used in a large variety of applications because of its particular combination of chemical and physical properties and because it is physiologically innocuous.

1. Introduction

Glycerol [*56-81-5*], $C_3H_8O_3$, M_r 92.09, 1,2,3-propanetriol, commonly known as glycerin, is the simplest triol. It can be found in all natural fats and oils as fatty esters and is an important intermediate in the metabolism of living organisms.

Glycerol was discovered in 1779 by Scheele through saponification of olive oil with lead oxide. In 1813, Chevreul showed that fats are glycerol esters of fatty acids. He also gave glycerol its name, after the Greek word $\gamma\lambda\upsilon\kappa\epsilon\varrho o\varsigma$ which

© 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a12_477.pub2

means sweet. The first industrial use of glycerol was in 1866 when NOBEL produced dynamite, in which the trinitrate of glycerol — nitroglycerin — is stabilized by absorption on diatomaceous earth.

The most important industrial synthesis of glycerol, which uses propene as starting material, was developed in the late 1930s by I.G. Farben in Germany and by Shell in the United States.

Glycerol is now used in a large variety of applications because of its particular combination of chemical and physical properties and because it is physiologically innocuous. Total production is estimated (1998) to be ca. 750 000 t/a; about 90 % is produced by processing natural oils or fats and 10 % is synthesized from propene [1, 2].

2. Physical Properties

Glycerol is a sweet-tasting hygroscopic liquid; when pure, it is colorless and odorless. At room temperature it is viscous.

The boiling point of glycerol is 290 °C at atmospheric pressure (101.3 kPa). The corresponding values under reduced pressure are listed in Table 1. With some liquids, (e.g., biphenyl), glycerol forms azeotropes; with others (e.g., water), nonazeotropic mixtures are formed. The vapor pressure curves of glycerol – water solutions at various glycerol concentrations are shown in Figure 1. The liquid – vapor equilibria of glycerol – water solutions, important for distillation and fractionation, have been established experimentally [3 – 5]. The boiling- and condensing curves at 13.3 and 1.33 kPa are shown in Figure 2. Suitable theoretical methods of calculation are also available [6].

Table 1. Vapor pressure vs. temperature of glycerol

Temperature, °C	Pressure, kPa
290	101.3
266	53.3
222	13.3
204	6.67
175	2.00
152	0.67
130	0.18
100	0.03
20	<0.0001

Figure 1. Vapor pressure of glycerol – water solutions (wt % glycerol) [7, 10]

Figure 2. Liquid–vapor equilibria for glycerol–water solutions
a) Boiling curve, 1.33 kPa; b) Boiling curve, 13.3 kPa; c) Condensing curve, 1.33 kPa; d) Condensing curve, 13.3 kPa

The freezing point of pure glycerol is ca. 18 °C. The crystalline state is seldom reached, however, because of a strong tendency toward supercooling. A solid, glassy state can be observed from ca. − 70 to − 110 °C. Crystallization can be brought about at ca. 0 °C by seeding with glycerol crystals. The freezing point

of glycerol – water solutions is shown in Figure 3. At 66.7 wt % glycerol, an eutectic mixture is formed, *fp* − 46.5 °C.

Figure 3. Freezing point of glycerol–water solutions

The density of glycerol is 1.261 g/cm^3 (20 °C). Tables of the density of glycerol – water solutions at various concentrations of glycerol are given in [7]. For rough estimations, a mean density change of 0.0007 g/cm^3 per unit change in temperature may be used in the range from 0 to 200 °C. The compressibility of glycerol is only about half that of water.

Figure 4. Dynamic viscosity of glycerol – water solutions

The refractive index of aqueous glycerol for the range 0 – 100 % glycerol is tabulated in 1 % steps in [7]. The viscosity of glycerol – water solutions (0 – 100 wt % glycerol) from − 40 to 100 °C has been determined [7]. Some curves are shown in Figure 4. Aqueous glycerol solutions, at any concentration, will supply moisture until equilibrium with water vapor in the atmosphere is reached [7]. The relative humidity over glycerol solutions is illustrated in Figure 5.

Figure 5. Relative humidity over aqueous glycerol (20 – 100 °C)

Glycerol has useful solvent properties, similar to those of water and simple aliphatic alcohols, because of its three hydroxyl groups. It is, accordingly, completely miscible with water, methanol, ethanol, and the isomers of propanol, butanol, and pentanol. It is also fully miscible with phenol, glycol, propanediols, amines, and heterocyclic compounds containing a nitrogen atom in the ring (e.g., pyridine, quinoline). Its solubility, however, is limited in acetone, diethyl ether, and dioxane. Glycerol is almost insoluble in hydrocarbons, long-chain aliphatic alcohols, fatty oils, and halogenated solvents such as chloroform. Ternary systems, such as glycerol – water – phenol and the nonaqueous system glycerol – ethanol – benzene, display significant temperature-dependent miscibility gaps. Glycerol also forms azeotropes with some other substances [8]. Glycerol is a useful solvent for many solids, both organic and

inorganic (e.g., see Table 2), which is particularly important for the preparation of pharmaceuticals. The solubility of gases in glycerol, like other liquids, is temperature- and pressure-dependent [9]. Some important physical properties of glycerol are presented in Table 2; a comprehensive collection of data is available [10].

Table 2. Physical properties of glycerol

M_r	92.09
mp	18.0 °C
bp (101.3 kPa)	290.0 °C
Density (20 °C)	1.261 g/cm^3
Refractive index n_D^{20}	1.4740
Dynamic viscosity (20 °C)	1.410 Pa · s

Heat of formation	−669 kJ/mol
Heat of combustion	−1662 kJ/mol
Heat of vaporization (55 °C)	88.2 kJ/mol
(195 °C)	76.1 kJ/mol
Heat of fusion (18 °C)	18.3 kJ/mol
Heat of solution (infinite dilution)	− 5.8 kJ/mol
Heat capacity (298 K $< T <$ 383 K)	$C_p(T) = 987.98 + 4.7074 \times T$ in J kg^{-1} K^{-1}
(− 80 °C)	1.91 kJ kg^{-1} K^{-1}
(− 108 °C)	0.91 kJ kg^{-1} K^{-1}
Thermal conductivity (0 °C)	0.29 W m^{-1} K^{-1}
Diffusion constant of water into glycerol (20 °C)	1.33×10^{-11} m^2/s
Specific electrical conductivity (20 °C)	0.1 µS/cm
Relative dielectric constant (25 °C)	42.48
Flash point	177 °C
Fire point	204 °C
Autoignition temperature on glass	429 °C
Calorific value	18 kJ/g
Solubility of KCl (99.5 % glycerol) (25 °C)	6.01 g/100 g
(90 °C)	8.78 g/100 g
Solubility of NaCl (99.5 % glycerol) (25 °C)	7.22 g/100 g
(90 °C)	7.31 g/100 g
Solubility of Na_2SO_4 (99.5 % glycerol) (25 °C)	0.20 g/100 g
(90 °C)	0.63 g/100 g
Solubility of N_2 (99.25 % glycerol) (15 °C)	0.553 vol %
Solubility of CO_2 (99.26 % glycerol) (15 °C)	43.8 vol %

3. Chemical Properties

Glycerol is a reactive molecule that undergoes all the usual reactions of alcohols (→ Alcohols, Aliphatic; → Alcohols, Polyhydric). The two terminal primary hydroxyl groups are slightly more reactive than the internal secondary hydroxyl group. In the presence of small amounts of strong mineral acid the odor of acrolein (odor threshold 0.2 – 0.4 ppm) is already quite perceptible at 160 °C. At 200 °C and more the formation of acrolein is vigorous. When heated under neutral or alkaline conditions, only traces of acrolein have been observed. At 180 °C, alkaline glycerol begins to dehydrate, forming ether-linked polyglycerols. At room temperature glycerol rapidly absorbs water; when dilute it is attacked by microorganisms. Glycerol is easily oxidized: the terminal carbon atoms to aldehyde or carboxyl groups and the central carbon atom to a carbonyl group [11, 12]. Biochemical oxidation of glycerol has also been described [13]. Catalytic hydrolysis [14] or microbial conversion [15] of glycerol to acrolein and 1,3-propanediol was also a topic of research.

Industrially important reaction products of glycerol include:

1) Mono-, di-, and triesters of inorganic and organic acids;
2) Mono- and diglycerides of fatty acids formed by transesterification of triglycerides (from fats);
3) Aliphatic and aromatic esters, formed by reaction with alkylating or arylating agents, respectively [16, 17];
4) Polyglycerols, formed by reaction of glycerol and epichlorohydrin with consecutive alkaline hydrolysis or by intermolecular elimination of water with alkaline catalysts;
5) Cyclic 1,2- or 1,3-acetals or ketals, formed by reaction with aldehydes or ketones, respectively;
6) Mono- or diglycerates, formed by the action of alkali or metal alcoholates.
7) Glycerol polyoxyalkylenes, formed by alkoxylation of glycerol(s) with ethylene- or propylene oxide under alkaline conditions.

In addition to these, there is a growing interest to oxidation products of glycerol and ethers, especially tert-butyl ethers (see Chapter 8).

4. Production

Glycerol is obtained as a byproduct in the conversion of fats and oils to fatty acids or fatty acid

methyl esters. This type of glycerol is known as natural or native glycerol, in contrast to synthetic glycerol from propene. Other methods of production (e.g., fermentation of sugar or hydrogenation of carbohydrates) are not industrially important.

The fastest growing source of glycerol is the production of fatty acid methyl esters for biodiesel (see → Automotive Fuels). In Europe alone the production in 2004 was 1.5×10^6 t and it is expected to increase to over 10×10^6 t by the year 2010. Per each tonne of biodiesel 100 kg of glycerol is formed.

In Europe the legislation requires the use of renewable components in fuels and another important factor enhancing the biodiesel introduction is the fact that for many countries it is produced from domestic raw material and thus it reduces the dependence from the imported oil. It is also an environmentally friendly source of energy.

4.1. Glycerol from Fats and Oils

Although a component of all vegetable and animal fats and oils, glycerol does not exist in the free form but as fatty acid esters; all three hydroxyl groups are usually esterified. Such esters are called triglycerides (→ Fats and Fatty Oils; → Fatty Acids). The glycerol content of fats and oils varies between 8 and 14 wt %, depending on the proportion of free acid and on the chain-length distribution of the fatty acid esters. To obtain glycerol, the oils and fats must be split hydrolytically.

4.1.1. Fat Splitting

(For a detailed description of processes used in the splitting of fats and oils see → Fatty Acids, Chap. 3)

Natural glycerol today is mainly produced by high-pressure splitting and transesterification. Glycerol from the neutral saponification of oils is encountered only in small quantities.

High-Pressure Splitting. Splitting under pressure has been known since 1854; continuous process reactors are now used. Water and fat are fed into a splitting column in countercurrent fashion at 2 – 6 MPa and 220 – 260 °C, leading to a ca. 15 % solution of glycerol in water, known as sweet water. This glycerol is marketed as 88 % saponification- or hydrolysis-crude glycerol. Such glycerol is extremely low in ash: a typical value is ca. 0.1 % or less of inorganic salts.

Transesterification. Natural crude glycerol of similar quality can be obtained from the transesterification (either high or low pressure regime [18]) of oils and fats to their methyl esters. Continuous processes are dominating. Glycerol from the low pressure transesterification process has a much higher salt content of 2 – 5 %. The crude glycerol is obtained directly at a concentration of ca. 90 – 92 %.

Saponification. The splitting of fats by saponification of neutral oils is a traditional method; caustic alkali or alkali carbonates are used, as in the production of soap (→ Soaps). The use of calcium hydroxide in the form of milk of lime is also possible.

4.1.2. Pretreatment and Concentration of Crude Glycerol

The pretreatment of glycerol water is an important step in the work-up, which is crucial for trouble-free production and for the quality of the final product. Glycerol water produced by high-pressure hydrolysis is slightly acidic. Dispersed fat and fatty acid components can be largely removed under these conditions simply by settling or by centrifugation. In a subsequent step the concentration is immediately increased to 70 – 90 % glycerol to avoid decomposition by fermentation (resulting in formation of 1,3-propanediol) and to render the crude product stable to storage. A multistage flash evaporator of stainless steel yields the greatest economic advantage. This main pretreatment takes place directly before final purification and refining.

An optimum treatment effect can be obtained in dilute solutions with a glycerol content of ca. 50 %. A two-step process is normally employed. Activated carbon and sodium hydroxide are used as auxiliaries, the former for bleaching and absorption of impurities, the latter to saponify any remaining fat components. A separation by filtration follows each step. The so-called soda-lime process has been valued for

Figure 6. Continuous glycerol distillation (Crown Iron Works Company)

decades for the pretreatment of crude glycerol contaminated with larger amounts of organic impurities [7]. The treated crude glycerol is further concentrated by distillative work-up. Single- or multiple-step plants are used with a vacuum of 10 – 15 kPa. The solubility limits of the salts must be taken into consideration, and the relevant stages suitably equipped for removal of the salt.

Desalination of crude glycerol is also possible by ion exclusion chromatography, using a cationic, strongly acidic exchange resin. The technique was originally developed in the sugar industry. The resin column is first fed with a certain amount of glycerol, the ionic substances remain in the liquid volume between the resin particles (Donnan effect), whereas the nonionic components concentrate in the resin pores. When the resin column is rinsed with water in the second step, the ionic substances are eluted first, followed by the nonionic compounds [19, 20]. By measuring density and conductivity, the process steps can be run completely automatically.

4.1.3. Purification and Refining

Until the end of the 1950s the large-scale production of pharmaceutical-grade glycerol was possible only by *distillation.* Batches were distilled under vacuum with fractional condensation. The development of new technologies allowed conversion to continuous production processes, with correspondingly low losses.

A glycerol refining unit used for the thermal work-up of crude pretreated and evaporated glycerol to glycerol of 99.5 % purity is shown in Figure 6 [21, 22]. For work-up of glycerol with a high salt content, *ion exclusion chromatography* [23] (see Section 4.1.2) or *thin-film distillation* is employed [24, 25]. The glycerol is spread by a rotor in a thin film onto the inner wall of an externally heated column and vaporized. The residue flows or trickles to the bottom. This equipment, combined with a fractionating column, is shown in Figure thin-film distillation is the extremely short residence time; thermal loading of the glycerol is thereby minimized. Refinement of diluted (40 – 50 % glycerol) low-salt crude glycerol can also be carried out by *ion exchange* (see Fig. 8). This process became available with the development of exchange resins

Figure 7. Continuous glycerol distillation (Cognis) [25]

Figure 8. Ion exchanger (principle diagram)

suitable for glycerol [26]. Ion exchangers are used in pairs and consist of a cationic and an anionic exchanger. Charged impurities are thereby successively removed and ultimately exchanged for water. The process permits removal of inorganic salts, fat and soap components, colored matter, odor-causing substances, and other impurities. The so-called adsorption resins possess special decolorizing properties; nonionic components such as chromophores can be removed physically by adsorption [27, 28].

The subsequent concentration of pharmaceutical-grade glycerol solutions is carried out under especially mild conditions to avoid changes in color and odor: a three- or four-step stainless steel flash evaporator with natural circulation is mostly used (Fig. 9).

Figure 9. Continuous glycerol concentration
a) Feed heater; b) Evaporator; c) Separator with demister; d) Water condenser; e) Glycerol heater; f) Glycerol heater/final product cooler; g) Falling film evaporator; h) Glycerol condenser

At 10 – 15 kPa, a glycerol concentration of ca. 90 – 95 % is attained. The removal of residual water to give a glycerol concentration > 99.5 % is best carried out in a separate final step by forced circulation in a falling-film evaporator. The vacuum used is 0.5 – 1.5 kPa. The continuous processes described above are suitable for automation when equipped with the appropriate control equipment.

4.2. Synthesis from Propene

Three processes are known for the production of glycerol from propene [*115-07-1*], involving the following intermediate stages (Fig. 10):

1) Allyl chloride – epichlorohydrin
2) Acrolein – allyl alcohol – glycidol
3) Propylene oxide – allyl alcohol – glycidol

Only the first of these is important industrially.

4.2.1. Production from Allyl Chloride

The first synthetic glycerol was produced in 1943 by I.G. Farben in Oppau and Heydebreck and in 1948 by Shell in Houston, Texas. This method became available once the high-temperature chlorination of propene to allyl chloride [*107-05-1*] could be controlled properly (→ Allyl Compounds, Chap. 1.3.1). The allyl chloride produced is oxidized with hypochlorite to dichlorohydrin, which is converted without isolation to epichlorohydrin [*106-89-8*] by ring closure with calcium or sodium hydroxide (→ Epoxides, Chap. 4.1). Hydrolysis to glycerol is carried out with sodium hydroxide or sodium carbonate [29 – 31].

Epichlorohydrin is hydrolyzed to glycerol at 80 – 200 °C with a 10 – 15 % aqueous solution of sodium hydroxide or sodium carbonate at atmospheric or overpressure. The residence time in one or a series of several closed, continuously operating reactors amounts to several minutes or several hours depending on the plant concerned. The yield of dilute (10 – 25 %) glycerol solution is > 98 %. The solution contains 5 – 10 % sodium chloride and less than 2 % of other impurities (Fig. 11). This aqueous glycerol solution containing sodium chloride is evaporated in a multistage evaporation plant under vacuum to a glycerol concentration of > 75 %; precipitated sodium chloride is separated at the same time (Fig. 12). The glycerol solution is then distilled under high vacuum (ca. 0.5 – 1.0 kPa) as shown, e.g., in Section 4.1.3, Figs. 6 and 7; codistilled water is separated by fractional condensation. Residual inorganic salts and higher oligomers

Figure 10. Routes for synthesis of glycerol from propene

of glycerol remaining after the evaporation must be worked up further or discarded. The glycerol, practically free of water, is treated further to remove colored impurities and odorous material; this can be performed, for example, with activated carbon.

Figure 11. Synthesis of glycerol from epichlorohydrin
a) Exhaust gas cooler; b) Circulation reactor

4.2.2. Production from Acrolein

The acrolein process for the production of glycerol was developed by Shell and does not require the use of chlorine [32]; the first plant was built in 1958 in Norco, Louisiana. Propene is oxidized to acrolein [*107-02-8*], which is then reduced to allyl alcohol [*107-18-6*] (Meerwein–Ponndorf–Verley reduction). The allyl alcohol is epoxidized with hydrogen peroxide, and the resulting glycidol [*556-52-5*] is hydrolyzed to glycerol.

4.2.3. Production from Propylene Oxide

As with acrolein, preparation of glycerol from propylene oxide does not use chlorine. Propene is epoxidized to propylene oxide, which is then isomerized to allyl alcohol by the Progil process [33] (→ Allyl Compounds, Chap. 2.3.2). A second epoxidation is carried out with peracetic acid, and the resulting glycidol is hydrolyzed to glycerol.

4.3. Other Processes

Fermentation of Sugar. The formation of glycerol by fermentation of alcohol was discovered in 1858 by Pasteur. Industrial use became possible once the mechanism was understood; the fermentation could be interrupted at the glyceraldehyde 3-phosphate stage with sodium carbonate or with alkali or alkaline earth sulfites. After reduction to glycerol phosphate, glycerol is obtained in yields up to 25 % by hydrolysis [34 – 37]. The process is economically unimportant.

Hydrogenation of Carbohydrates. Hydrogenation of natural polyalcohols such as cellulose, starch, or sugar leads to mixtures of glycerol and glycols, which can be separated by distillation. Catalysts used in this high-temperature

Figure 12. Three-stage evaporation plant for aqueous glycerol solutions: Buss glycerol evaporation process [24]
a) Evaporator vessel; b) Reboiler; c) Cyclone; d) Vacuum pump; e) Centrifuge; f) Stirred tank; g) Storage tank for glycerol solution

reaction include nickel, copper, cobalt, chromium, and tungsten, as well as oxides of some of the lanthanides [38].

Other Noncommercial Processes. Glycerol can be obtained in yields of ca. 7 % by enzymatic splitting of fats and oils with lipases in special reactors [39 – 41] (→ Fatty Acids, Chap. 3.2.3).

Photoproduction of glycerol along with other biomass is possible by means of solar energy and algae [42, 43]. Another synthetic process involves the catalytic hydrogenation of carbon monoxide [44].

5. Environmental Protection

Ecologically, glycerol presents no special problems. Discussion of environmental protection is limited to those industrial processes based on fats and oils and on epichlorohydrin, because only these processes are economically important.

5.1. Production from Fats and Oils

Production Plants. No special protective measures are necessary for the work-up of natural crude glycerol with the technology described above.

Gaseous Emissions. Certain measures are necessary to prevent atmospheric pollution by odors during storage and purification of native crude glycerol. Exhaust vapor from the respective tanks and process units should be drawn off and treated (e.g., burned) in a closed system (→ Fatty Acids, Chap. 7).

Residues. The residues of higher glycerol oligomers and inorganic salts remaining from evaporation and distillation are water soluble and must be treated further, recycled, or disposed of properly.

5.2. Production from Epichlorohydrin

Extensive protective measures must be taken to allow proper handling of epichlorohydrin, because of the hazardous properties of this material (→ Epoxides). Regulations exist in several countries concerning exhaust gas and wastewater purification as well as measures for the protection of plant personnel.

Production Plants. Production plants must be explosionproof to prevent ignition of epichlorohydrin. Manipulation of epichlorohydrin exclusively in closed systems guarantees protection of personnel.

Gaseous Emissions. Epichlorohydrin and accompanying organic material in exhaust gases from the hydrolysis of epichlorohydrin can be removed, for example, by adsorption on activated carbon or can be incinerated.

Wastewater. Wastewater contaminated with epichlorohydrin can be treated with alkali, thereby converting the epichlorohydrin to glycerol.

Residues. Residues from evaporation and distillation should be treated as described in Section 5.1.

5.3. Environmentally Important Properties of Glycerol

Gaseous Emissions. No problems are encountered with gaseous emissions because of the low vapor pressure of glycerol and the lack of odor of the pure material.

Wastewater. Glycerol poses no problems for wastewater because it is completely and readily biodegradable in sewage treatment plants according to OECD classifications. Glycerol is not regarded as dangerous to the water supply: the relevant values are: COD = 1217 mg of O_2 per gram; BOD_5= 780 mg of O_2 per gram. The fish toxicity is >100 mg/L (LC_{50} according to acute fish toxicity test OECD 203). Local regulations regarding wastewater must be taken into account.

6. Quality Specifications and Analysis

Glycerol can be detected qualitatively by heating a small sample with potassium hydrogen sulfate; the presence of glycerol is indicated by the characteristic pungent odor of acrolein.

The most accurate wet method for quantitative determination of glycerol is periodate oxidation. Glycerol is oxidized by sodium periodate to formaldehyde and formic acid:

$$\underset{}{\overset{OH}{\overset{|}{CH_2}}}-\overset{OH}{\overset{|}{CH}}-\overset{OH}{\overset{|}{CH_2}} + 2\ NaIO_4 \longrightarrow 2\ HCHO + HCOOH + H_2O + 2\ NaIO_3$$

Formic acid is determined by titration and is a measure of the amount of glycerol; polyols with three or more neighboring hydroxyl groups (e.g., sugars) interfere. For quantitative determination of impurities in glycerol gas chromatography is employed.

Natural and synthetic glycerols can be distinguished by site-specific natural isotope fractionation nuclear magnetic resonance spectroscopy (SNIF – NMR) and isotope ratio mass spectroscopy (IRMS) [45, 46]. Water in glycerol can be determined quantitatively by Karl Fischer titration or by near infrared spectroscopy (NIR). A rapid method for establishing the glycerol content of commercial glycerol–water mixtures is measurement of the refractive index at 20 °C or determination of the density with a digital instrument that electronically measures the period of oscillation of a swinging body suspended in the glycerol [47]. In contrast, measurement of the density with a pycnometer is, for the same degree of accuracy (0.1 %), considerably more time consuming. Color is given as Hazen or APHA color number; typical color values would be 5 – 20, depending on the glycerol quality. For rapid measurement, equipment is available for direct color comparison with standardized slides. Ash, heavy metals, chloride and organic chlorine compounds, pH, and acidic or alkaline substances can be determined by standard analytical methods or by methods given in various pharmacopoeias. Traces of reducing agents, such as aldehydes, sometimes still present in glycerol can be determined quantitatively by special tests, e.g., with silver nitrate.

Glycerol is sold in crude (natural glycerol) or pure form. In the latter, a distinction is made between various grades that are linked with given sets of specifications and analytical methods:

- Technical glycerol at various concentrations (e.g., Nobel test glycerol 99.5 %, Glycerol 99.8 %)
- Pharmaceutical grade (e.g., Ph. Eur., U.S.P., Japanese Pharmacopoeia): Glycerol Ph. Eur. 85 %, Glycerol Ph. Eur.
- Food grades [e.g. E 422 (EU-directives 98/86/EC, 95/2/EC), Food Chemical Codex grade (FCC); generally recognized as safe (GRAS § 182.1320) for human consumption by the U.S. FDA].

7. Storage and Transportation

Storage. Glycerol should preferably be stored at 40 – 60 °C under nitrogen blanketing. It is not corrosive and presents little risk of ignition because of its high flash point. Highly concentrated glycerol does not corrode steel, but storage tanks of carbon steel must be protected by surface coating to prevent rusting by residual moisture. Glycerol is therefore usually stored in tanks of stainless steel [48, 49] or aluminum. Regulations exist in some countri es to control the construction and arrangement of industrial storage tanks.

Transportation. Glycerol is shipped in tank trucks, containers, and drums. The tank trucks and containers are usually made of stainless steel. Galvanized or resin-coated steel as well as plastic is used for drums.

8. Derivatives

8.1. Esters

Glycerol forms esters with both inorganic and organic acids; depending on reaction conditions and degree of esterification, these can be mono-, di-, or triglycerides. Of most importance are esters produced from nitric, acetic, and fatty acids [7, 51].

Glycerol trinitrate [*55-63-0*], nitroglycerin, is produced in a mixture of nitric and sulfuric acids. It is used as an explosive and pharmaceutical.

The *acetins* are produced industrially by esterification of glycerol with acetic acid, acetic anhydride, or both. They are the most important esters of glycerol from short-chain carboxylic acids. The greatest use is of triacetin.

Glycerol fatty esters, the partial glycerides, are obtained by transesterification of fats or oils with glycerol to a mixture of mono- and diglycerides. The mono- and diesters of fatty acids are edible, as are the triglycerides.

8.2. Chlorohydrins

Chlorohydrins are treated in a separate keyword (→ Chlorohydrins); epichlorohydrin see → Epoxides, Chap. 4.1.

8.3. Oxidation Products

The oxidation products of glycerol are presented in Figure [13]. The components derived from glycerol are valuable intermediates for fine and specialty chemicals and some of them are useful as such. Their current and common production methods involve complex organic syntheses, fermentation and multiple step reactions and the production costs are high and amounts of produced waste are large. Selective catalysed reactions from glycerol offer benefits in reduced productions costs, increased selectivity and reduced amounts of waste and solvents. Studies are concentrated on heterogeneous catalysis and supported platinum and palladium are regarded as the best catalysts for glycerol oxidation e.g.,[52, 53]. Also supported gold catalysts [54] as well as some homogeneous catalysts, such as TEMPO (2,2,6,6-tetramethylpiperidine-1-oxyl) [55], are studied.

Figure 13. Oxidation products of glycerol

8.4. tert-Butyl Ethers

Glycerol can be etherified with alkenes and especially etherification with isobutene to produce

tert-butyl ethers of glycerol is regarded interesting [56 – 60]. Depending on the extent of the etherification reaction various products are formed. Altogether five isomers are formed as 1–3 hydroxyl groups in glycerol molecule can be etherified and also isomers exist (Fig. [14]). The product distribution can be controlled by process conditions, e.g., temperature and feed compo -sition.

Figure 14. *tert*-Butyl ethers of glycerol

9. Use of Glycerol and its Derivatives

Today, glycerol has more than 2000 different applications that arise from its properties: glycerol is water-soluble, is odor- and colorless, has a certain sweetness, absorbs and retains water, has a capacity to dissolve flavors and dyes, has plasticizer properties, protects against fermentation processes, has antioxidant properties, is nontoxic and easily biodegradable and is a polyol. Information on areas of application is available in the literature [61]; over 800 references are cited in [62] alone. Consumption of glycerol according to major applications is shown in Figure 15.

Figure 15. Applications of glycerol (worldwide)

9.1. Use in Foods, Cosmetics, and Pharmaceuticals

Foods. In beverages, syrups, and flavor extracts glycerol is applied as a solvent for the preparation of concentrated flavor extracts from natural products such as vanillin or spices. Furthermore, it is a carrier for many dyes and synthetic flavor compositions and has a good compatibility with sucrose for the preparations of concentrated syrups. Glycerol as such or in the form of its monoglycerides improve s the texture and extends the shelf life of baked goods. Glycerol is used as a conditioner for wine gums, fondants, soft creams, or pastilles. Fruits and vegetables are sprayed with glycerol to keep them in fresh conditions. Mono- and diglycerides are main emulsifiers in ice-cream production, they improve texture, stability and melting properties; in margarine, th ey improve texture and water retention. Glycerol esters of acetic and tartaric esters are used as emulsifiers in bread production; citric acid esters are used in sausages and meat products, and lactic acid esters serve, e.g., as emulsifier for desserts. Glycerol is applied as a moisturizer in sweets and dried fruits to prevent loss of water followed by shrinkage and is a preservative for fish, poultry, and meat [62].

Cosmetics. In cosmetics and toiletries glycerol is mainly used of its chemical properties (formation of esters that serve as emulsifiers or conditioners), moisturizing, and conditioning

properties. Glycerol finds application in creams, lotions, and preparations for skin and hair care as well as in tooth pastes and dental mouthwashes [63].

Pharmaceutical applications of glycerol arise from its conditioning, self-preserving, and dissolving properties in syrups, ointments, and parenteral solutions. Glycerol trinitrate is an important drug for the treatment of angina pectoris. Glycerol also is used as a mild laxative in suppositories. It is a softener in gelatin capsules and suppositories [64].

9.2. Use in Plastics, Resins, and Cellophane

The polyfunctional reactivity of glycerol is used in the production of phthalic and maleic alkyd resins (→ Alkyd Resins) and in cross-linked polyesters from mono- and dicarboxylic acids and polyols. Polyether polyols made of glycerol in combination with propylene- and ethylene oxide are polymerized with diisocyanates in the presence of highly volatile solvents to form flexible or rigid polyurethane foams. Glycerol also serves as a moisturizer and plasticiz er in cellulose films.

9.3. Use in Tobacco Industry

Glycerol is in use as a solvent for flavor compositions for tobacco. It also serves as a humidifier and plasticizer for the tobacco. Glycerol triacetate (triacetin) is used as a softener for cigarette filters.

9.4. Other Applications

Glycerol is used as a hydraulic agent and in hydraulic fluid formulations. Technical esters of glycerol with fatty acids are in use for synthetic lubricants in the automotive industry and as lubricants in the food industry. They are used for readily and totally biodegradable loss lubrication, e.g., in the agriculture and forest industries. Polyglycerols have a wide range of applications as emulsifiers. Inks and printing colors contain glycerol to prolong their servic life. The paper industry uses glycerol a s a humidifier, plasticizer, and lubricant.

9.5. Future Applications

tert-Butyl ethers of glycerol have mainly been studied for fuel applications. The octane numbers for the ether product mixture are 112-128 (BRON) and 91-99 (BMON) [65] and these values indicate that in this sense they are suitable to be used as gasoline components. However, these products are not yet in commercial production, but other ethers resembling their structure, such as MTBE (methyl-*tert*-butyl ether) and ETBE (ethyl-*tert*-butyl ether), are currently used in gasoline as high -octane components. The oxygen-containing components, i.e., oxygenates have been observed to enhance the burning of the fuel resulting in cleaner burning and less-harmful exhaust gases.

The ethers are mainly studied for the gasoline applications but it has also been suggested that they could be used as biodiesel additive [66]. The addition of the ethers in the biodiesel decreases the viscosity, cloud point, and pour point which enables the fuel to be used in lower temperature. Thus the properties of biodiesel are brought closer to conventional diesel fuel.

10. Economic Aspects

Estimated worldwide consumption of glycerol amounts to ca. 750 000 t/a; about 65 % of the total production is in Europe and the United States. Annual production (10^3 t) is shown in Figure 16.

The fraction of synthetic glycerol is ca. 10 %.

The price of glycerol is subject to fluctuation. In times of higher prices, glycerol is partly replaced in certain applications by products such as glycols or sorbitol. Nevertheless, the consumption of glycerol increased from 550 000 t to 750 000 t from 1986 to 1998 corresponding to an increase of ca. 3 % per year.

As glycerol is a byproduct in many processes its production rate is not dependent on the market demand. Since 1995 there has been oversupply of glycerol in the world market and the increasing production of biodiesel increases the oversupply further. It has been estimated that by

the year 2020 the production is six times more than the demand.

Figure 16. Annual production of glycerol (worldwide)

11. Toxicology

Glycerol is not harmful to health. Oral doses have a demulcent and mildly laxative effect. Ingestion of large amounts may produce headache, thirst, nausea, and hyperglycemia. Slight irritation of the skin or mucous membranes is possible on contact with undiluted glycerol because the strongly hygroscopic glycerol absorbs water from the skin.

There is no glycerol-specific aerosol limit. However, in UK and USA the recommended general long-term (8-hour TWA) exposure limit for aerosols is 10 mg/m^3 and has also to be observed for glycerol mists.

1. Introduction

Glyoxal [*107-22-2*], ethanedial, diformyl, $C_2H_2O_2$, M_r 58.04, was first prepared in 1856 by Debus, through the controlled oxidation of ethanol with nitric acid [1].

2. Physical Properties

Anhydrous glyoxal is a liquid at ambient temperature; it crystallizes at 15 °C in the form of yellow prismatic crystals and boils at 50.4 °C (101.3 kPa), giving off green vapors with a pungent odor. The liquid has a specific gravity of 1.14 at 20 °C; $n_D^{20.5} = 1.3826$. Electron diffraction and infrared spectra show that the molecule is planar; the trans configuration is the more stable [2].

3. Chemical Properties

As the simplest dialdehyde, glyoxal undergoes reactions characteristic of aldehydes (→Aldehydes, Aliphatic and Araliphatic, Chap. 2.2.).

Anhydrous monomeric glyoxal can be obtained by heating polyglyoxal in the presence of phosphorus pentoxide. Anhydrous glyoxal polymerizes rapidly under the action of traces of water, forming a series of hydrated oligomers. Glyoxal is used only as an aqueous solution, at concentrations between 30 and 50 %. Evaporation of this solution produces a white, solid mass of polyglyoxal, which is infusible, depolymerizes upon heating, and decomposes above 150 °C.

In 40 % aqueous solution, glyoxal exists mainly in the form of the hydrated monomer (**1**), together with a dioxolane dimer (**2**) and two bis(dioxolane) trimers (**3**); these components represent ca. 80 % of its total composition [3].

In concentrated aqueous solution the most abundant component is the hydrated trimer (**3**), which is responsible for the cloudiness or crystalline precipitates in aqueous glyoxal solutions.

More highly condensed oligomers are also present, as shown by ^1H and ^{13}C NMR during acetalization by low molecular mass primary alcohols [4]; the species present have been quantified as a function of concentration and temperature.

With alcohols, under acid catalysis, a mixture of oligomeric acetals is obtained. Glycolates are also formed; glycolate formation predominates in the presence of a strong acid [5]. Glyoxal acetals and thioacetals are used as complex-forming agents [6].

10.1002/14356007.a12_491

With primary amines glyoxal forms diimines, reduction of which leads to ethylenediamines, [7] which are used industrially to cross-link isocyanates in coatings.

Glyoxal reacts with β-hydroxyalkylamines to give a heterodecalin:

With diethanolamine [*111-42-2*], the final product is *N,N*-bis(2-hydroxyethyl)glycine [*150-25-4*] (R = $-CH_2CH_2OH$):

The latter is used to form complexes with polyvalent cations (see also → Ethylenediaminetetraacetic Acid and Related Chelating Agents) [8].

The corresponding aminoacetamides are formed with secondary amines [9], [10]:

Controlled oxidation leads successively to glyoxylic acid [*298-12-4*] and oxalic acid [*144-62-7*] [11], [12].

With aldehydes and enolizable ketones, glyoxal leads to the expected aldol condensation products [13]; e.g., with acetone or isobutyraldehyde:

With amides and urethanes, di- and tetramides are obtained, depending on the pH [14], [15].

In alkaline medium, glyoxal disproportionates by an internal Cannizzaro reaction to the glycolate [16–18]:

4. Production

Among the numerous processes for producing glyoxal, only those using *acetaldehyde* [*75-07-0*] and *ethylene glycol* [*107-21-1*] as starting materials have been developed commercially.

From Acetaldehyde. Oxidation with nitric acid was examined by LJUBOWIN as early as 1875 and patented in 1942 [19]. Reaction takes place at ca. 40 °C and is carried out industrially as a continuous process. Maximum yield is ca. 70 %; selectivity is a function of the relative concentrations of reagents. After the removal of ex-

cess acetaldehyde, the glyoxal formed, which is contaminated with acetic, formic, and glyoxylic acids, is purified by passage of the aqueous solution through an ion-exchange resin. The solution is then concentrated to a glyoxal content of about 40 %.

Selenium oxide [*7446-08-4*] is more selective than nitric acid, and the yield is ca. 84 %; the selenium can be recycled by oxidation with hydrogen peroxide [20]. This process has not been carried out on an industrial scale.

From Ethylene Glycol. The gas-phase oxidation of ethylene glycol by atmospheric oxygen in the presence of dehydrogenation catalysts (metallic copper or silver) represents the basis of the Laporte process [21] and has been used in several industrial production processes. Reaction occurs between 400 and 600 °C; the yield is 70 – 80 %. The main impurity is formaldehyde [*50-00-0*], whose subsequent separation is difficult. This reaction has also been carried out in the liquid phase and under irradiation.

Other Processes. Ethylene can be oxidized by aqueous nitric acid in the presence of palladium [22], by atmospheric oxygen, or by selenium oxide deposited on silica [23]. Glyoxal may also be formed by oxidation of acetylene [24] or benzene [25] with ozone. Ethylene oxide has been proposed as a substrate for oxidation. Although oxalic acid and its derivatives can be reduced to glyoxal, these processes have not been developed further.

5. Uses

Glyoxal is supplied mainly as a 40 % aqueous solution. Various polyhydroxy polymers (e.g., starch or poly(vinyl alcohol)) can be used to stabilize glyoxal.

The bifunctionality of glyoxal has been used to cross-link functionalized macromolecules such as cellulose, polyacrylamides, poly(vinyl alcohol), keratin, and other polycondensates. For example, glyoxal is used as a cross-linking agent for imparting wet strength to coated paper. With cellulose, unstable hemiacetals are obtained in the cold, which irreversibly form acetals when heated in the presence of acid catalysts [26].

The dual functionality and the ability of glyoxal to form heterocyclic compounds have been used in the production of resins for imparting crease resistance to textiles. The reaction proceeds through the intermediate formation of 4,5-dihydroxy-2-imidazolidinone (**4**) [*3720-97-6*] (DHEU) and its methylolated derivatives (DMDHEU).

4

Ethers of DMDHEU are among the most effective resins for the crease-resistant treatment of cotton-based fabrics [27], [28].

The reducing properties of glyoxal are used in the photographic industry and in glassmaking for the production of silvered glass mirrors.

Glyoxal bisulfite (available as the monohydrate) is used as a resist agent in printing with reactive dyes and as a leveling agent in dyeing polyamide with acid dyes.

An important class of molecules used as cross-linking agents is obtained by nucleophilic substitution of glyoxal. Examples include the bisacrylamide (**5**) [*76843-24-8*] and the tetraallylacetal (**6**) [*16646-44-9*].

5

6

Glyoxalbisacrylamide is used for the functionalization of ion-exchange resins and in latices for treating textiles. Tetraallyloxyethane is used as a cross-linking agent for polyacrylates (→Polyacrylates) and for pressure-sensitive adhesives.

Glyoxal is used in the fine chemicals industry for the production of various heterocyclic compounds including tetraacetylgly-

coluril [*10543-60-9*] (**7**) (a perborate accelerator), imidazoles such as metronidazole [*443-48-1*] (**8**) that are effective against anaerobic bacteria, and the pyrazine derivatives sulfapyrazine [*116-44-9*] (**9**), thionazine [*297-97-2*] (**10**), and pyrazinamide [*98-96-4*] (**11**).

7

8

9

10

11

Glyoxal has bactericidal properties comparable with those of glutaraldehyde and is used as a disinfectant.

6. Toxicology and Occupational Health

Glyoxal has low toxicity. The LD_{50} is 3300 mg/kg (oral, rat). No mortality was observed in rats at a dosage of 1.3 mg/L inhaled in a saturated atmosphere or with aerosols. Glyoxal was well tolerated topically in a rabbit skin test but was irritating to the eyes. Glyoxal causes an allergic sensitization in guinea pigs.

Glyoxal gives a positive result in the Ames mutagenesis test, but it does not change cells in the cell transformation test and has no elastogenic effect in the micronucleus test; it is also not mutagenic in the Chinese hamster lung test. All of these tests are generally positive with substances known to be mutagenic.

1. Introduction

Glyoxylic acid [*298-12-4*], oxoacetic acid, glyoxalic acid, OHC−COOH, M_r 74.04, is the simplest α-oxocarboxylic acid. It is found in plants and is involved in the metabolic cycle of animals. Glyoxylic acid was discovered by Debus, who established its formula in 1856 [1]. This formula was described more precisely as that of the monohydrate by Perkin in 1868 [2].

In 1957, Kronberg and Krebs established the basis of the metabolic cycle of glyoxylic acid [3], in which isocitrate is converted to malate anaerobically. This cycle acts as a relay in the tricarboxylic acid cycle under specific conditions of plant life, such as germination or ineffective photosynthesis [4], [5].

2. Physical Properties

Glyoxylic acid crystallizes as the monohydrate upon controlled concentration of its aqueous solution. When dry, the monohydrate has *mp* 52 – 53 °C. The dissociation constant in aqueous solution is 4.7×10^{-4}, and the specific heat is 1.80 kJ kg^{-1} K^{-1}. The density of a 50 % aqueous solution of the acid, the only commercial form, is 1.34 g/cm^3 at 20 °C; the refractive index (20 °C) is 1.416.

The use of NMR spectroscopy (^{1}H [6] and ^{13}C [7]) has confirmed the existence of glyoxylic acid in aqueous solution as the dihydroxy acid (**1**) together with a small proportion of the linear dimer (**2**).

1

2

Glyoxylic acid is strongly hydrophilic; it is soluble in alcohols, with which it reacts, and in water-miscible solvents; it has a very low solubility in ether and other organic solvents.

Glyoxylic acid forms complexes with ions of alkali and alkaline-earth metals; it has a chelating power of 30 mg of calcium carbonate per gram of 50 % aqueous solution.

3. Chemical Properties

Glyoxylic acid contains two functional groups: the carbonyl group, which undergoes reactions characteristic of aldehydes (→Aldehydes, Aliphatic and Araliphatic, Chap. 2.2.), and the carboxylic acid group (→Carboxylic Acids, Aliphatic, Chap. 3.). The aldehyde group reacts readily with nucleophilic reagents; the hydrated aldehyde and the hemiacetal react similarly. With ambident nucleophiles, the carboxylic group may also react, leading to intramolecular ring formation. Various heterocyclic compounds can be obtained by coupling polynucleophiles with glyoxylic acid: *o*-phenylenediamine [*95-54-5*] gives 2-hydroxyquinoxaline [*1196-57-2*] (**3**); with urea [*57-13-6*] and an acid catalyst, allantoin [*97-59-6*] (**4**) is obtained in 60 % yield [8].

3

4

On heating, glyoxylic acid disproportionates to a mixture of glycolic acid [*79-14-1*] and oxalic acid [*144-62-7*]; glyoxylic acid is also easily oxidized to oxalic acid by nitric acid.

Reactions that have been used industrially include the Mannich reaction and amidoalkylation. Thus, with phenol and ethylenediamine in alkaline medium, glyoxylic acid leads to the sodium salt of *N,N′*-ethylenebis[2-(2-hydroxyphenyl)glycine] (EHPG, **5**), which forms complexes with iron (III) [9].

Glyoxylic acid, phenol, and ammonia react to give 4-hydroxyphenylglycine, an intermediate for the semisynthetic penicillin amoxicillin [10] (see →Antibiotics).

At slightly alkaline pH, glyoxylic acid reacts with amides such as acrylamide [*79-06-1*] to form acrylamidoglycolic acid (AGA), which is used as a copolymerizable cross-linking agent [11] (→Polyacrylamides and Poly(Acrylic Acids)).

Several derivatives of AGA have found industrial application; e.g., the methyl ether ester is used in coatings and paint for automobiles.

Glyoxylic acid combines with phenol in alkaline medium to give 4-hydroxymandelic acid with good selectivity [12].

The reaction with phenols is used in several industrial syntheses of benzaldehydes. For example, guaiacol [*90-05-1*] is converted to vanillin [*121-33-5*] by oxidative decarboxylation of the corresponding mandelic acid [13].

The mandelic acid intermediate may be modified further: reaction of phenol and glyoxylic acid in the presence of a reducing agent such as phosphorus – iodine leads directly to hydroxyphenylacetic acid [14], a building block for pharmaceuticals such as Atenolol.

With thiophene, this reaction yields 2-thienylacetic acid, which is used to prepare the semisynthetic cephalosporins cephalothin and cefoxitin.

Glyoxylic acid and hydrochloric acid can be used to chloroalkylate aromatic compounds [15].

Glyoxylic acid undergoes the aldol reaction; the corresponding benzoylacrylic acids are obtained with acetophenones [16]:

Glyoxylic acid is treated with Wittig ylides to form carboxyl functional polyenes of the vitamin A type [17].

Esters of glyoxylic acid, obtained by dehydrative distillation of the hemiacetal esters in the presence of phosphorus pentoxide, can be polymerized under the action of a base. After saponification, the resulting polymers show useful chelating properties with the advantage of good biodegradability [18], [19]. Low molecular mass polyglyoxylates have been proposed as substitutes for sodium tripolyphosphates (TPP) in detergents to control water hardness.

4. Production

Glyoxylic acid is produced industrially by oxidation of glyoxal in aqueous solution with 65 % nitric acid in mole ratios of 1 : 1 to 1 : 1.5 between 40 and 90 °C. The main byproduct of this process is oxalic acid, which is separated by low-temperature crystallization. The solution is then purified by passage through an anion-exchange resin or by electrodialysis, which removes the residual nitric acid.

Glyoxal can also be oxidized at the anode of a two-compartment electrolytic cell in the presence of chloride ion [20]. Glyoxylic acid may be synthesized by catalytic oxidation of ethylene or acetaldehyde, but the selectivity is low and these routes have not been used industrially.

The cathodic reduction of oxalic acid gives a very good chemical yield (85 %), but this technique encounters problems with passivation of the lead electrodes [21], [22].

Another method is oxidative cleavage of maleic acid or its esters by ozone. This process, has been adapted to the preparation of hemiacetal esters [23].

5. Toxicology

The LD_{50} is 2500 mg/kg (oral, rat). Glyoxylic acid is corrosive to the eye (rabbit), does not irritate the skin, but causes an allergic sensitization in guinea pigs. No mutagenic effect was found in the Ames mutagenicity test; glyoxylic acid is completely inactive in the so-called micronucleus mutagenicity test in mice.

Glyoxylic acid is a metabolite in mammalian biochemical pathways.

1. History [1–24]

1.1. Centers of Gold Production

Gold is the first element that humans recognized as a metal. Towards the end of the Middle Stone Age and the onset of the Neolithic Age (ca. 8000 B.C.), the world's climate changed greatly. Large areas became arid, necessitating the establishment of permanent settlements in river valleys such as the Euphrates, the Tigris, and the Nile. The earliest archeological findings that can be reliably dated were made in predynastic Egypt (ca. 4000 B.C.) and Mesopotamia, which the Sumerians settled in 3000 B.C. Outstanding finds (ca. 3000 B.C.) were made close to modern Varna, on the Bulgarian shores of the Black Sea. Gold was first mentioned in literature in the Indian Vedanta (before 1000 B.C.), the writings of Herodotus (484 – 425 B.C.), and the Old Testament (1000 B.C.).

The historical development of gold processing and important gold production centers are summarized in Figure 1. Egypt was the principal gold country in the pre-Christian era and maintained that status until ca. 1500 B.C. Gold production reached its peak about 1300 B.C. when the first legal foundations for the production of gold were laid, awarding the Pharaoh the absolute monopoly. In ca. 2700 B.C. gold rings were introduced as means of payment; the first gold coins appeared around 600 B.C.

The origin of the gold used by the Egyptians is unclear. Substantial portions appear to have come from Nubia in Upper Egypt (nub = gold), but considerable quantities were probably imported following the frequently mentioned expeditions to "Punt."

The special status enjoyed by gold in Egypt also exerted an influence in neighboring countries. The country of Ophir mentioned by Solomon as the origin of his gold may be identical with Punt, but India may also have been the supplier. The Egyptian gold trade expanded particularly under the impetus of the seafaring Phoenicians and Greeks.

Although Egypt was the principal gold country until about 1 B.C., gold was also found and utilized in other regions including India, Ireland, Bohemia, the Carpathian Mountains, Gaul, on the Iberian peninsula, and in the Caucasus.

Even in ancient times the ownership of gold shifted from one ruler to the other through conquests and the collection of tributes. Alexander the Great obtained possession of Indian gold as well as considerable portions of the Pharaohs' treasure. The Romans had little of the metal in their own regions but their military expeditions netted them major amounts in the form of booty; they also exploited the mineral wealth of the countries they had conquered, especially Spain, where up to 40 000 slaves were employed in mining. The state's accumulation of gold bars and coins was immense. Later, however, more and more gold was used in luxury goods and towards the end of the Roman empire a gold shortage was experienced.

In the region corresponding to modern-day Zimbabwe, organized gold production existed prior to 1000 A.D.

The advent of Christianity in the Middle Ages reduced the general striving for gold. Moreover, until the beginning of the Middle Ages no dominant political power existed for organizing large-scale gold production. In Europe, only the deposits in the Sudeten mountains, the Carpathians, and the Alps were of any significance. Out-

side Europe, gold was produced in India, Japan, and Siberia.

Following the discovery of America and the rapid conquest of the New World at the end of the fifteenth century, the Spaniards transferred considerable amounts of gold from the New World to Europe. Although the conquistadors found a highly developed mining industry in Central America, their efforts to increase gold production were largely unsuccessful; most of the finds consisted of silver. It was not until the discovery of deposits in Brazil that there was a noticeable

increase in world gold production. These deposits were exploited from 1725 to about 1800.

Since about 1750 gold has been mined on a major scale on the eastern slopes of the Ural mountains. In 1840, alluvial gold was discovered in Siberia. The Russian deposits were exploited by the Czars and the land owners, who had to pay their taxes in gold. Russia produced about one fifth of the world's gold production, a proportion maintained until the present day.

The discovery of gold in California in 1848 increased gold production greatly. The special laws issued in the Western parts of the United States allowed private mining thanks to the right to stake claims. This type of working continued when gold deposits were found in Eastern Australia (1851), Nevada (1859), Colorado (1875), Alaska (1886), New Zealand and Western Australia (1892), and Western Canada (1896). However, these deposits soon lost much of their importance.

The strongest impetus was given to gold production through the discovery of the goldfields of the Witwatersrand in South Africa in 1885. This extremely rich deposit appeared to guarantee steady exploitation far into the future. South African gold soon occupied a commanding position in the world market. Production grew continuously except for a short interruption by the Boer War (1899 – 1902). In the 1970s, gold production largely stabilized in South Africa and in the rest of the world. In South Africa, several hundred thousand people are now employed in the production of gold.

The discovery of large deposits of gold in Brazil in the 1970s stimulated prospecting activities. New production centers have been established in the Sierra Pelada of Brazil, Canada, Venezuela, New Guinea (Ok Tedi), and especially Western Australia, causing a pronounced shift in the geographic distribution of world gold production.

Gold mining in Ghana (Gold Coast) only began to play a role, if a modest one, in the twentieth century, although the deposits were already known in the Middle Ages. Gold production in Zimbabwe and the neighboring eastern part of the South African bush veld today form a moderate but not insignificant part in the overall production of southern Africa.

1.2. Production

Total gold production in antiquity can only be assessed approximately. Up to the fall of the Roman Empire, production may have amounted to 10 000 t.

A total production figure of 2000 – 3000 t has been quoted for the Middle Ages. By the time of the discovery of America, annual world production had reached about 5 t.

An annual production of ca. 10 t was reached in ca. 1700, rising to ca. 15 t in 1800 and to 40 t by 1848, the year the Californian deposits were discovered. As early as 1852, more than 200 t/a were mined, but production subsequently decreased until 1890. Thereafter, the increased output of the South African mines raised annual world production to 500 t in 1904, 700 t in 1907, and 1000 t in 1936. Since then, world annual production, which was at times subject to major fluctuations, has risen to over 2000 t. A further 300 t/a result from industrial recycling.

The total world production of gold in 1991 exceeds $1.09\ 10^5$ t [187]. More than a third of the present-day gold inventory is held by the central banks of the Western industrialized nations as currency backing. An even larger proportion is in private hands, much of it in the form of jewelry. Krugerrands alone accounted for 2000 t in 1967 – 1985, and smaller quantities are circulating in industry.

The shares of individual states in the overall production until now are divided among the Republic of South Africa (40 %), the United States (15 %), the ancient empires (ca. 10 %), Russia/CIS (ca. 10 %), Australia and the Pacific Region (ca. 10 %), and Canada (ca. 5 %).

1.3. Development of Production Processes [25–27]

The development of gold production processes is summarized in Figure 1. In antiquity, gold grains obtained by washing river sands were cold-worked into the desired objects. From ca. 3900 B.C., alluvial gold could be fused into larger lumps. The ancient Egyptians were the first to quarry gold-bearing rocks. Comminution of the rocks and washing were often preceded by heat treatment.

Analyses of archeological finds show that, in Egypt, the separation of gold from silver and copper was feasible, possibly as early as 2000 B.C. Silver was removed by annealing with common salt to give silver chloride [8]. The naturally occurring gold – silver alloy, electrum magicum, was separated into its constituents. The slagging of copper by adding lead followed by cupellation was also known.

In Spain, the Romans developed the technique of flush mining, by which vast masses of rock were dropped from a height, comminuted, and moved by currents of water. Amalgamation presumably originated at that time, although it was first mentioned in the literature in the 11th century A.D.

In the Middle Ages, fusion with lead and cupellation were developed further. Water-powered crushing machines were also introduced for pulverizing ore, and miners learned to process arsenic-containing gold ores by roasting.

The alchemists endeavored to manufacture gold by transmutation of base metals. It was not until the end of the 18th century that the entire concept was finally rejected as false. However, these endeavors led to a better understanding of chemical processes and to the birth of the true natural sciences.

The 17th century saw the discovery of separation by inquartation, i.e., the separation of gold and silver by nitric acid, and of affination, i.e., separation by sulfuric acid. With advancing industrialization in the 19th century new methods replaced the old, but some of the latter have retained some importance to this day. Production of gold as a byproduct of other metallurgical processes, (e.g., the refining of copper, zinc, and lead), played an increasingly important role in Germany (Rammelsberg/Harz). In 1863, Plattner's method of chlorination was introduced in the United States and shortly afterwards in Australia. In 1867, MILLER succeeded in refining gold with chlorine. Refining by electrolysis according to WOHLWILL was introduced in 1878 and is still used for all fine gold of 9995 and 9999 purity. Since 1888, cyanide leaching has permitted economical beneficiation of the Witwatersrand ores, which were less amenable to other methods due to the extremely fine distribution of the gold. Since 1970, conventional cyanide leaching has been superseded by the carbon-in-pulp process, which dispenses with filtration of the leached rock powder. More recently, the ecological problems caused by cyanide leaching have been overcome by treating the cyanide in the wastewater with hydrogen peroxide.

The recent expansion of gold production is also due to the mechanization of ore transportation and beneficiation. In South America, however, manual mining of ores is once again being resorted to. This politically motivated measure, taken with a view to creating jobs, made employment possible for 500 000 people.

Solvent extraction is being investigated as a relatively new method for the rapid and effective refining of fine gold.

2. Properties [1], [20], [22], [28–37]

The distinction between noble and base metals is in many ways arbitrary, and is generally determined by practical considerations and tradition. Gold is the classic noble metal and complies with all the criteria for this group of elements: resistance to air, humidity, and to normal wear. Gold is also remarkable among the metals in that it occurs in nature almost exclusively in its elementary state.

2.1. Physical Properties

Gold, atomic number 79, atomic mass 196.96654, has only one naturally occurring isotope, ^{197}Au. Its most important radioisotope, which is used in medicine, is ^{195}Au; it emits ε and γ rays and has a half-life of 183 d. The electronic configuration of gold is $[Xe]\,4f^{14}\,5d^{10}\,6s^{1}$. Its atomic radius is 0.1442 nm. The ionic radius for coordination number 6 is 0.1379 nm for Au^{+}, and 0.085 nm for Au^{3+}.

Some physical properties of gold are as follows:

mp	1064.43 °C
bp	2808 °C
Density at 20 °C	19.32 g/cm^3
at 900 °C	18.32 g/cm^3
at 1000 °C	18.32 g/cm^3
at 1065 °C	17.32 g/cm^3
at 1200 °C	17.12 g/cm^3
at 1300 °C	17.00 g/cm^3

Vapor pressure at 1064 °C	0.002 Pa
at 1319 °C	0.1 Pa
at 1616 °C	10 Pa
at 1810 °C	100 Pa
at 2360 °C	10 000 Pa
Atomic volume at 20 °C	10.21 cm^3/mol
Electrical resistivity at 0 °C	2.06×10^{-6} Ω cm
Thermal conductivity at 0 °C	3.14 W cm^{-1} K^{-1}
Specific heat	0.138 J g^{-1} K^{-1}
Enthalpy of fusion	12.77 kJ/mol
Enthalpy of vaporization	324.4 kJ/mol
Tensile strength	127.5 N/mm^2

The melting point of gold has been a fixed point on the temperature scale since 1968.

The unit cell of gold is face-centered cubic (type A1), with a lattice constant (a_0) of 0.40781 nm. Gold as it occurs in nature usually does not have a very crystalline appearance. It exhibits threadlike, leaf-shaped, and spherical forms, on which cubic, octahedral, and dodecahedral surfaces can sometimes be seen. When large amounts of molten gold solidify, a characteristic pattern of concentric rings appears on the surface.

Pure gold that has not been mechanically pretreated is very soft. Its hardness on the Mohs' scale is 2.5, and its Brinell hardness is 18 HB. Gold is the most ductile of all metals. It can be cold drawn to give wires of less than 10 µm diameter, and beaten into gold foil with a thickness of 0.2 µm (see Section 8.4). Because of its softness, gold can be highly polished; this, together with its noble characteristics and brilliant color, gives it its yellow luster. The color of utility gold is less rich and varies considerably according to its alloy composition (see Chap. 8). Very thin gold foil is translucent; transmitted light appears blue-green.

The physical properties of gold and its alloys have been thoroughly investigated because of their significance for modern technology. For detailed information see [22], [28], [36], [37].

2.2. Chemical Properties [38]

Gold does not react with water, dry or humid air, oxygen (even at high temperature), ozone, nitrogen, hydrogen, fluorine, iodine, sulfur, and hydrogen sulfide under normal conditions.

Sulfuric acid, hydrochloric acid, hydrofluoric acid, phosphoric acid, halide-free nitric acid (except in very high concentrations), and practically all organic acids have no effect on gold, either in concentrated or dilute solutions and at temperatures up to the boiling point. If a hydrohalic acid is combined with an oxidizing agent, such as nitric acid, a halogen, hydrogen peroxide, or chromic acid, gold will dissolve. Gold can also be dissolved in a combination of water and a halogen (the Plattner process) and in selenic acid. Figure 2 shows the dissolution rates of gold in the most important industrial agents used for its dissolution.

Aqueous solutions of alkali metal hydroxides, alkali metal salts of the mineral acids, and alkali metal sulfides do not attack gold. However, gold dissolves in solutions of alkali metal cyanides in the presence of oxygen (see Fig. 2 and Section 4.2) or other oxidizing agents, such as cyanogen bromide (the Diehl process), 4-nitrobenzoic acid (see Fig. 2) and 3-nitrobenzenesulfonic acid, provided they do not rapidly destroy the cyanide. Gold is also attacked by sodium thiosulfate solutions in the presence of oxygen, and by alkali metal polysulfide solutions.

Fused caustic alkalis do not attack gold, provided air and other oxidizing agents are excluded. Gold reacts vigorously with alkali metal peroxides to form aurates. It is inert to the alkali metal phosphates and borates, and to the alkali metal salts of the mineral acids, which can therefore be used as slagging agents for removing metallic impurities from gold.

Gold reacts readily with dry chlorine. The maximum reactivity occurs at 250 °C, and the minimum at 475 °C. Above 475 °C the reactivity increases with increasing temperature up to and beyond the melting point.

Gold can be recovered from solution by electrolytic deposition or by chemical reduction. If the tetrachloroaurate(III) complex is present, then iron(II) salts, tin(II) salts, sulfur dioxide, hydrazine, hydrazonium salts, oxalic acid, or ascorbic acid can be used as reducing agents. The very stable dicyanoaurate complex requires stronger reducing agents such as zinc. Anion exchangers, which are used for the recovery of gold from solutions, sometimes reduce this complex to metallic gold. Similar results are achieved with activated carbon.

The standard potential of Au/Au^{3+} is +1.498 V, of Au/Au^{+} +1.68 V, and of Au^{+}/Au^{3+} +1.29 V.

Figure 2. Rate of dissolution of fine gold sheet metal in various oxidizing agents
a) Aqua regia, 6 mol/L; b) HCl, 6 mol/L + Br_2, 0.2 mol/L; c) NaCN, 0.45 mol/L + 4-nitrobenzoic acid, 0.1 mol/L + NaOH, 0.2 mol/L; d) HCl, 6 mol/L + Cl_2 (saturated); e) HCl, 6 mol/L + H_2O_2, 0.22 mol/L; f) NaCN, 1 mol/L + air; g) NaCN, 0.45 mol/L + NaOH, 0.2 mol/L + air; h) NaCN, 0.006 mol/L + $Ca(OH)_2$, 0.004 mol/L + air

Gold can be alloyed with many other metals. In classic metallurgical processes (e.g., the lead blast furnace process and the reverberatory furnace process for copper ore), gold and silver follow the same route. Zinc, lead, and copper act as collecting agents for gold through the formation of alloys. Gold exhibits the greatest affinity for zinc, followed by lead, and then copper. Zinc is used to remove gold from molten lead in the Parkes process (→ Lead). The readiness with which gold takes up lead, tellurium, selenium, antimony, and bismuth is a disadvantage, particularly with regard to subsequent mechanical processing. Gold alloys readily with mercury at room temperature to form an amalgam. The mercury can be distilled out by heating. This property is utilized in the amalgamation process (see Section 4.1), and in fire gilding (see Section 10.8).

Colloidal gold forms hydrosols of an intense red or violet color, which are relatively resistant even without protective colloids.

3. Occurrence [1], [2], [6], [20], [40–45]

3.1. Abundance

Gold is distributed very unevenly in the Earth's crust, mainly due to enriching processes that have taken place near the surface. Its average abundance is very low and is estimated at ca. 0.005 ppm, although widely varying figures are given.

The gold content of ocean water also varies greatly, depending on the location. Gold contents of 0.008 – 4 mg/m^3 (ppb) have been reported.

3.2. Gold Deposits [7], [11], [44]

The gold deposits which are most easily recognized, and which were the earliest to be discovered, are enriched veins and deposits of gold particles. These particles were originally present in primary rock that was worn down by weathering. Enrichment then followed with partial consolidation due to flowing water. Such deposits are known as *placer* or *secondary deposits.* Typical examples are the relatively small

gold deposits in the Rhine Valley, California, and Alaska. The abundance of gold in placer deposits fluctuates greatly especially as the gold particles may be concentrated in very small areas, e.g., a stream bed. Under favorable conditions, placer deposits containing as little as 1 ppm gold may be successfully exploited.

Quartz veins containing gold are often found along the fault plane of rock fractures. As the gold particles have remained at their place of origin, these are termed *primary deposits.* In general, it can be assumed that this gold has been formed hydrothermally, i.e., it has been through an intermediate stage in aqueous solution. Such deposits are found in East Africa, Australia, Canada, and the Soviet Union. Their gold content varies greatly.

The Witwatersrand goldfields in the Republic of South Africa (Transvaal and Orange Free State) were also formed by sedimentation. These are sand and shingle deposits that have been compacted to form massive rock, in which the gold is distributed as very fine particles. This type of gold deposit is known as a *conglomerate deposit.* The average gold content of the ore when separated from the gangue is ca. 12 ppm. Mining reaches a depth of 4000 m where temperatures of 60 – 70 °C can prevail. Work is only possible here with cooling, which is performed with chilled air, cooled water, or ice [21]. To date about one-third of the total world gold production has been derived from the Witwatersrand conglomerate ore. The waste extracted sand which is found, for example, around Johannesburg, contains about 1500 t gold (0.5 ppm), mainly contained in pyrites (FeS_2) which is not dissolved by cyanide treatment. This material can also be processed economically.

Sulfidic copper ores may have gold inclusions which can become highly concentrated as a result of weathering. In the outer oxidation zone, hydrothermal reactions take place, such as

$$3\,Fe^{3+} + Au \xrightarrow{H_2O} Au^{3+} + 3\,Fe^{2+}$$

while in the underlying cementation zones, the corresponding back reaction occurs. Such deposits are found in Papua New Guinea (Ok Tedi) and in Brazil. The Ok Tedi deposit contains about 4 ppm of gold in the cementation zone.

Copper sulfide ores normally contain only a small proportion of gold (< 1 ppm); however, they can be a significant gold source. During smelting, gold accompanies silver and can be separated in the copper anode slimes. Practically all silver ores also contain some gold.

3.3. Gold Reserves and Resources

The term reserves denotes those resources whose existence has been established by prospecting and for which mining is economically viable.

World gold ore reserves are assessed at 75 000 t in 1991, or less than 40 times the world annual primary production [187]. In 1970, gold reserves were calculated to be one-fifth of this amount. At that time, the extensive Brazilian and southeast Asian deposits had not been discovered.

Of the reserves known today, 40 % are found in the Republic of South Africa, 35 % in Brazil, and 15 % in Russia/CIS. These are followed by the United States, Canada, Australia, China, Borneo, Papua New Guinea, Zimbabwe, and Ghana, with 1 – 5 % each.

4. Production [1], [2], [20], [27], [35], [39], [45–56]

4.1. Ore Treatment

In many places, gold is still mined by individuals and converted on the spot into marketable raw gold using simple manual and mechanical processes, such as panning (gravity separation), milling, and amalgamation. Amalgamation is carried out by allowing a slurry of ground gold-containing ore to flow over mercury-coated copper plates. The resulting gold amalgam is periodically removed by scraping. Very fine gold particles cannot be recovered by these methods, and in many cases, especially in Brazil, the use of cyanidation (see Sections 4.2 and 4.3) to extract the residual gold has been proposed.

Where gold is found in river sands covering a large area, the ore is often mined and processed in floating dredgers. This type of mining is found, for example, in Siberia, and in the north of the American continent.

In the conglomerate gold deposits in Witwatersrand, South Africa, most of the gold occurs as very fine particles. This means that mechanical enrichment and amalgamation are impossible, and the gold must be converted to a soluble form by reaction with sodium cyanide. For this purpose, the gold particles are first released from the rock material by means of breakers, wet ball mills, and classifiers. In newer plants, this milling process takes place underground.

Ground gold ore that contains large gold particles or sulfides may be unsuitable for cyanidation. Pretreatment, consisting of gravity concentration, generally followed by amalgamation, is therefore nearly always necessary; this also allows up to 50 % of the gold to be extracted faster than by the cyanidation process.

Gravity concentration

was formerly carried out using a cord cloth. The cloth was laid on a suitable support, and a water slurry of ground ore was passed over it, the grooves in the cloth being arranged at right angles to the direction of flow. The denser particles were retained in the grooves, while the lighter quartz particles flowed away with the water.

The cord cloth has now been replaced by corrugated rubber (thickness 10 mm, groove depth 3 mm, distance between grooves 6 mm). Modern mechanical equipment has endless belts (width 1.5 m, length 7.2 m), tilted at an angle of 11°. These advance at a speed of 0.4 m/min, against the direction of flow of the ore slurry. The concentrate is sprayed off with water and sent to the amalgamation plant. In place of endless belts, slowly rotating cylinders lined with corrugated rubber are sometimes used (length 3.6 m, diameter 0.9 m, inclination 3.75°).

Concentrates from gravity separation processes cannot be directly melted down into gold bars, because they contain considerable amounts of iron pyrites and metallic iron. Gold and silver are therefore generally separated from these components by *amalgamation.* The concentrate, which has a water content of about 70 %, is filled into a cast iron drum (length 0.9 m, diameter 0.6 m) containing steel balls (diameter 50 mm). The drum is rotated for 12 h, after which the gold particles are free from all impurities. Mercury is then added, and the drum is rotated for a further 2 h. The resulting amalgam is separated from the other components in a hydrocyclone (diameter 200 mm, inclination 20°); water and excess mercury are removed in a filter press. Remaining mercury is removed by distillation, leaving an impure mass of spongy gold, which is melted down into gold bars.

A *flotation process* is often used before gravity concentration in cases where the gold is closely associated with pyritiferous materials.

Roasting of ores in air is a secondary process which is sometimes used after gravity separation or flotation. The resulting oxides are then washed and treated by cyanidation. Gold ores containing sulfidic minerals can also be treated in a *bioleaching* process (see → Liquid – Solid Extraction, Chap. 3.3.3.), which dissolves the sulfides, exposing the gold particles for subsequent cyanidation.

4.2. Cyanidation [48]

The cyanidation process has been used in South Africa since 1890. In this process, the powdered mineral slurry, which contains ca. 10 ppm gold in the solid matter, is treated with an aerated 0.03 % sodium cyanide solution. Black cyanide ($Ca(CN)_2$ containing carbon and sodium chloride as impurities), a product of American Cyanimid, is often used instead of the more expensive sodium cyanide. The addition of calcium oxide ensures that the solution remains slightly alkaline. Dissolution takes place according to the following reaction:

$$4\,Au + 8\,NaCN + 2\,H_2O + O_2 \longrightarrow 4\,Na[Au(CN)_2] + 4\,NaOH$$

The dead powdered mineral is filtered off in large rotary vacuum filters. The filter cake contains less than a tenth of the original gold content of the ore. The filtrate is treated with zinc chips, which are preactivated in lead acetate solution, to precipitate the gold:

$$2\,Na[Au(CN)_2] + Zn \longrightarrow Na_2[Zn(CN)_4] + 2\,Au$$

The raw gold is treated with sulfuric acid to remove excess zinc, dried, and then roasted in air at 800 °C to oxidize lead, zinc, and iron. A flux, usually borax, is added, and the material is melted down to raw gold, with a gold content of 80 – 90 %.

An ecological problem is caused by the presence of sodium cyanide in the cake of dead rock

material and in the wastewater. However, when exposed to air and sunlight, the cyanide is converted to nontoxic cyanate, and subsequently carbonate.

4.3. Recovery of Gold with Carbon

[57–69]

The first mention of the ability of carbon to adsorb precious metals was made in 1847. In 1880, it was found that gold can be recovered from chlorinated leach liquors by wood charcoal. McArthur and the Forest brothers discovered that cyanide was a good lixiviant for gold in 1890 and, in 1894, charcoal was used to recover gold from cyanide solutions. The charcoal was prepared from wood and did not possess the high surface area and porosity of carbon today. As no elution procedure was known, the gold was recovered from the carbon by smelting. The use of carbon reached a high point of efficiency in Australia in 1917 when fine carbon was used to recover gold from pregnant cyanide solution, but, as the zinc cementation process advanced, so interest in the use of carbon dropped off.

In the 1940s, a carbon of higher activity and greater abrasion resistance was developed from fruit pips and, in 1952, an elution procedure involving the use of sodium hydroxide and cyanide (the caustic – cyanide procedure) was developed. In 1960, a plant using carbon was erected in Canada, and the first major carbon-in-pulp (CIP) plant to treat the fraction from which the coarse material has been removed (slimes) was built in the United States at Homestake in 1973 to treat 2200 t/d.

Major developments in CIP continued in South Africa, for treatment of the total cyanided pulp. By 1976, a small pilot plant was in operation and, by 1978, a plant processing 250 t/d was on line. The CIP process is now the preferred method worldwide for the recovery of gold from cyanided pulp. The only exception appears to be the Soviet Union, where the resin-in-pulp process is used. The CIP process is used for the treatment of a variety of feed materials ranging from run-of-mine ore to dump materials and roaster-bed products.

The advantages of the CIP process over zinc cementation are:

1) Capital costs are lower.
2) Operating costs are lower.
3) The ability of carbon to adsorb gold is not affected by any of the common constituents of leach liquors.
4) Carbon is added directly to the cyanided pulp, and therefore the need for the expensive filtration and clarification stage is avoided.
5) The losses of soluble gold are usually lower than in the zinc cementation process.
6) Ores that contain carbonaceous material can be processed without loss of gold to the carbonaceous fraction.
7) Materials that are difficult to filter or thicken can be treated successfully.

4.3.1. Adsorption of Gold by Carbon

Activated carbon has a porous structure (→ Carbon, Chap. 5.). The following theories have been proposed for the mechanism by which activated carbon loads gold cyanide:

1) complete reduction to metal
2) a chemical precipitation mechanism involving gold, carbon monoxide, and cyanide
3) physical adsorption of sodium dicyanoaurate(I)
4) adsorption of the dicyanoaurate(I) ion
5) ion-exchange adsorption of the dicyanoaurate(I) ion
6) adsorption of a neutral complex, whose nature is pH dependent
7) electrostatic interaction between the dicyanoaurate(I) ion and positively charged sites
8) a physisorption process
9) a two-step process, in which an ion pair is adsorbed onto carbon, and then reduced to an unidentified species.

The last-mentioned theory is now generally accepted.

The adsorption of gold cyanide onto activated carbon is reversible. Thus, an equilibrium exists between the gold in solution and the gold loaded on the carbon. Factors which affect the rate of gold adsorption and those which affect the equilibrium loading of gold are listed in Table 1.

Certain materials poison activated carbon for gold adsorption. Calcium carbonate can form in

the pores and is detrimental to adsorption, but is removed by acid-washing. Organic materials (e.g., machine lubricants, detergents, flotation reagents) also poison carbon to some extent, but are removed during reactivation. Lower adsorption efficiencies are attained when a pulp containing calcine, shale, or clay is used, since these finely divided minerals can block the pores. Copper can decrease efficiency of adsorption by competing with gold for adsorption sites, particularly at low concentrations of cyanide.

Table 1. Factors influencing the adsorption of gold by carbon

Factor	Effect of increasing the factor	
	on rate	on equilibrium loading of gold
pH	slight decrease	decrease
Ionic strength	slight decrease	increase
Free cyanide	slight decrease	decrease
Temperature	slight increase	decrease
Base metals	decrease	decrease
Carbon particle size	decrease	none
Mixing intensity	increase	none
Pulp density	decrease	none

4.3.2. Carbon-in-Pulp Process

Ores containing 0.25 – 100 g/t gold are processed in CIP plants at tonnages from 100 – 10^6 t per month. The density of the pulp varies from 1.3 to 1.45 g/cm^3, depending on its viscosity.

A schematic of a CIP plant is shown in Figure 3. The cyanided pulp is prescreened to remove coarse material that would otherwise move with the carbon granules, and might later block the screens in the CIP circuit. The pulp then flows through a series of six or eight flat-bottomed, cylindrical, agitated tanks. The residence time of the pulp in each stage is ca. 1 h. Reactivated carbon is added to the last stage, and is moved countercurrent to the flow of pulp. The carbon is held in each stage by interstage screens. The residence time of the carbon in each stage is 1 – 2 d. The carbon concentration in a CIP circuit is 15 – 30 g per liter of pulp. The barren pulp leaving the circuit is screened to remove fine carbon.

The loaded carbon, which contains 200 – 20 000 g of gold per ton, is removed periodically from the first stage and eluted with a caustic – cyanide solution. The carbon is washed with acid to remove calcium carbonate, and then reactivated at high temperature in a kiln. The gold in the eluate is generally recovered by electrowinning.

For reasons of economy, the CIP process is carried out underground in some mines.

Screening. The total pulp fraction has to be *prescreened* at a smaller aperture (0.6 mm, 28 mesh) than that of the interstage screens. Prescreening removes coarse material to avoid blocking of the screens further downstream. Two types of screen are used: (1) vibrating screens with woven wire or polyurethane mesh, and (2) linear moving-belt screens.

Wood chips constitute a small fraction of the incoming pulp, and cause problems further downstream when vibrating screens are used. Another prescreening device, such as a dummy tank, is then required. A dummy-tank is a closed circuit tank in which the pulp passes through submerged air-cleaned screens to remove wood chips.

Interstage screens are used to retain carbon while allowing the finer pulp to flow down through the train.

The two types of screen that are used are external and submerged. With *external screens,* the pulp is air lifted onto the screens (normally vibrating decks), and transferred to the next stage, while the carbon is returned to the stage from which it came. A number of *submerged screens* have been developed. Air-cleaned screens normally use square metal mesh, while mechanically cleaned screens use wedge-wire. Duties on these screens vary from 50 to 200 m^3 of pulp per square meter of screen per hour. The aperture of the screens is 0.8 mm (20 mesh). The size of the carbon particles used in CIP is 1 – 2 mm (8 to 16 mesh), although larger particles are used when problems are encountered with screening.

Abraded carbon resulting from breakage of the carbon in the CIP circuit is recovered from the barren pulp by a *final screen.* The units and apertures of this screen are similar to those used for prescreening.

Interstage movement of carbon is achieved using airlift pumps, vertical spindle pumps, centrifugal pumps, or peristaltic pumps.

Factors that affect the choice of pump are controllability, carbon wear, and operating costs. In most plants, carbon is transferred intermittently,

Figure 3. Schematic of the carbon-in-pulp circuit
a) Prescreening; b) Final screening; c) Regeneration; d) Elution; e) Electrowinning

but may also be transferred continuously. The following methods are used:

1) Loaded carbon is removed from stage one, the carbon in stage two is then transferred to stage one, and so on down the train.
2) Regenerated carbon is added to the last stage, the carbon in the last stage is then transferred to the second-last stage, and so on up the train.
3) All the pumps are turned on to transfer the carbon in each stage to the next stage up the train.

Agitation. The optimum agitation system provides a high pulp flow and low shear to avoid carbon breakage. Mechanical agitation is favored over air agitation because it consumes less power, provides better "live" vessel volume, and has acceptable carbon-attrition rates. Draft tubes and open-impeller agitators are used. Power inputs vary from 0.015 to 0.2 kW/m^3 of pulp.

Elution. The gold capacity of carbon decreases with increasing temperature. Increasing the concentration of cyanide and hydroxide ions also decreases the capacity of the carbon for gold.

These two facts were exploited by Zadra in 1952 to develop the first efficient elution technique to remove gold from carbon. Other elution procedures have since been developed.

The *Zadra process* involves the recycling of a solution containing 1 – 2 % sodium cyanide and 1 – 2 % sodium hydroxide through a bed of carbon. The temperature is over 85 °C, and the flowrate is about one bed volume per hour. The elution takes 48 h to complete. An electrowinning cell is used to recover the gold from the eluate. The advantages of this system are that the capital costs are low, the process is simple, and the reagent consumption is low. Its major disadvantage is that the rate of stripping is slow.

The *AARL process,* which was developed by the Anglo American Research Laboratories, has two stages. In the first stage, the carbon is presoaked under pressure at a temperature above 115 °C, in a solution containing 1 – 5 % sodium cyanide and 1 – 5 % sodium hydroxide for several hours. In the second stage, the carbon is eluted with five to seven bed volumes of water at 50 – 100 kPa and above 110 °C for 5 h at a flowrate of three bed volumes per hour. The advantages of this procedure are that elution is fast and the gold concentration in the eluate is high, which leads to efficient electrolysis. Its disad-

vantages include the need for high-quality water, more expensive equipment than that used by the Zadra process, and higher reagent consumption.

Elution with Organic Solvents. The addition of, for example, a 20 % solution of ethanol to a caustic – cyanide eluant increases the rate of elution, which takes ca. 6 h at atmospheric pressure and 80 °C. Disadvantages include higher reagent costs and handling problems associated with organic solvents.

The *high-pressure stripping process* is similar to the Zadra process, except that elution is carried out at up to 160 °C and at ca. 350 kPa. It has the advantages of lower reagent consumption, smaller elution inventory, and a smaller elution circuit. Disadvantages are more costly equipment, and that effluent solutions have to be cooled to avoid flashing.

Gold Recovery. The gold is recovered from the eluate either by zinc precipitation or by electrowinning. A number of electrowinning cells have been developed.

The *Zadra cylindrical cell* consists of a cylindrical core (polypropylene basket), which contains steel wool and acts as the cathode. The anode (stainless steel) surrounds the cathode in the cell, and the eluate is pumped into the center.

The most commonly used cell is the *Mintek cell.* It has a rectangular configuration with alternating anodes and cathodes in parallel, similar to those in copper-electrowinning cells. The cathodes are removable plastic baskets with perforated sides, packed with steel wool. The anodes are perforated stainless-steel plates. The flow of eluate is parallel to the flow of current.

Regeneration of carbon is carried out in two stages: (1) washing with acid to remove calcium carbonate and some base metals, and (2) thermal reactivation to remove organic materials and reexpose the pore structure.

The loaded carbon is washed with a 5 % solution of hydrochloric acid for 6 h at 75 °C in a column constructed of Hastelloy or rubber-lined mild steel. The carbon is then neutralized with sodium hydroxide. Acid-washing can be carried out before or after elution, but is generally done first because this increases the efficiency of elution.

In thermal reactivation, the degree of activation increases with increasing temperature and residence time, but micropores are destroyed if the conditions are too harsh. Reactivation is typically carried out at 700 °C for 10 min. Air should be excluded during regeneration. The steam generated from the carbon is normally sufficient to exclude air. The regenerated carbon is normally cooled by quenching in water.

Regeneration is usually carried out in a *rotary kiln,* which is heated externally by electrical resistive windings. In the *Rintoul furnace,* heating is achieved by passing an electric current through a bed of predried carbon in the presence of steam.

4.3.3. Carbon-in-Leach Process

Some ores contain carbonaceous material that is slightly active and can adsorb dissolved gold. These carbonaceous materials are termed preg-robbers. When a preg-robber is present in an ore, the carbon-in-leach (CIL) process is used, in which cyanidation and carbon adsorption occur in the same reactor.

The CIL circuit is similar to a CIP circuit, the main difference being the residence time of the pulp, since in CIL this is determined by the rate of gold dissolution and not by the rate of gold adsorption as in CIP. Hence, residence times of 4 h per stage are used. The presence of activated carbon prevents the preg-robber from adsorbing gold.

5. Gold Refining [1], [20], [27], [35], [39], [46], [47], [51], [53], [55]

5.1. Chemical Refining [2], [70]

The historical methods for separating gold from silver depended on dissolving silver and any accompanying base metals from solid solutions containing gold, using either nitric acid (inquartation) or sulfuric acid (affination) (Section 1.3). They were accepted up to the second half of the nineteenth century as the best way of manufacturing relatively pure gold. However, the exclusive use of these methods is insufficient today, and they must hence be combined with the other purification steps described below.

A method which allows recovery of relatively pure gold is to dissolve the raw gold in hydrochloric acid in the presence of an oxidizing agent. Silver chloride precipitates and can be removed, while gold is precipitated by reduction with oxalic acid or other reducing agents like $FeCl_2$, $FeSO_4$, SO_2, or Na_2SO_3. However, a single reductive precipitation process is usually insufficient, as part of any palladium present is entrained by the gold. If sulfur dioxide is used instead, the same applies to copper, nickel, zinc, and lead. Precipitation and separation normally have to be repeated several times before fine gold of sufficient purity is obtained. This method has therefore only found acceptance in cases where the commoner processes (see Sections 5.2 and 5.3) have not been established, either because the amounts involved are too small, or because the need arises only sporadically or in combination with other raffination processes like electrolysis. However, acid dissolution has several advantages: the metal is tied up for a short time only; a high yield of gold can be obtained in a single process step; and conventional equipment can be used.

5.2. Miller Process [71]

The Miller process has been of commercial significance since the 1870s. Probably more than two thirds of all gold produced to date has been through this process. It is extremely economical, and the gold quality obtained (99.5 – 99.6 %) meets the requirements of the gold trade. The largest plant in the world is the Rand Refinery in Gerniston, Republic of South Africa, which refines all the gold from South African mines, as well as that from neighboring countries. The Miller process is used not only by the mining companies of almost all gold-producing countries, but also in recycling processes.

The Miller process is based on the fact that gold chlorides are unstable above 400 °C, and thus do not form at a reaction temperature of ca. 1100 °C, whereas silver and base metals react with chlorine to form stable chlorides. At this temperature, AgCl (*bp* 1554 °C) and CuCl (*bp* 1490 °C) are molten and therefore collect in a slag layer, which is considerably less dense than molten gold. The chlorides of the other metals volatilize at the reaction temperature, for example, $PbCl_2$ (*bp* 954 °C), $FeCl_2$ (*bp* 1023 °C), $FeCl_3$ (*bp* 319 °C), $ZnCl_2$ (*bp* 732 °C), and $CuCl_2$ (*bp* 655 °C). As the process is effective when only a slight excess of chlorine is used, the amount of CuCl and $FeCl_2$ formed is greater than that of $CuCl_2$ and $FeCl_3$.

The raw gold delivered to the Rand refinery is weighed to an accuracy of 0.01 oz and then melted in an induction furnace. Four samples are taken and analyzed for gold content. The gold is cast into bars and reweighed. The gold content of the whole load is then determined. The bars are remelted in an induction furnace in batches of 500 kg, and chlorine gas is passed into the molten metal through quartz pipes, at a pressure of 0.2 kPa. First, the chlorine reacts selectively with iron, zinc, and lead (Fig. 4), whose chlorides are volatile at the reaction temperature and are thus removed as vapors. Finally, silver and copper chlorides form (Fig. 4). These are molten at the reaction temperature and thus form a slag which floats on the molten gold. Borax is added to the slag as a flux. The end point of the reaction is indicated by the appearance of red gold chloride vapor, and is confirmed by taking a sample for analysis. The silver content, which is determined by X-ray fluorescence analysis, must be below 0.4 %. After pouring off the slag, the gold is poured into tared molds.

Figure 4. Decrease in the concentration of impurities in gold as a function of chlorination time
∗ Expressed as a percentage of the initial metal content. Typical starting concentrations, wt %: Ag 9.0, Cu 1.4, Pb 0.35, Fe 0.18, Zn 0.06

The chloride slag is ground and screened. Entrained gold is separated and returned to the process. Copper(I) chloride is oxidized to copper(II) chloride using sodium chlorate solution containing hydrochloric acid, and dissolved. The

solution is filtered and copper is cemented. Silver chloride is reduced with zinc in aqueous solution, and sent to a silver-refining electrolysis process.

Platinum-group metals cannot be separated by the Miller process (Fig. 5), as their chlorides, like those of gold, do not exist at the reaction temperature. However, this is not a disadvantage for gold from the Witwatersrand deposits, as this is free from platinum-group metals.

Figure 5. Thermodynamic of the Miller process [22, p. 39] (Courtesy Giesel Verlag).
1) $Pt + 2\,Cl_2 \longrightarrow PtCl_4$;
2) $Pt + 2\,Cl_2 \longrightarrow PtCl_2$;
3) $Au + 1\frac{1}{2}\,Cl_2 \longrightarrow AuCl_3$;
4) $Au + \frac{1}{2}\,Cl_2 \longrightarrow AuCl$;
5) $Ag + \frac{1}{2}\,Cl_2 \longrightarrow AgCl$;
6) $Cu + \frac{1}{2}\,Cl_2 \longrightarrow CuCl$;
7) $Cu + Cl_2 \longrightarrow CuCl_2$;
8) $Ni + Cl_2 \longrightarrow NiCl_2$;
9) $Fe + Cl_2 \longrightarrow FeCl_2$;
10) $Pb + Cl_2 \longrightarrow PbCl_2$;
11) $Zn + Cl_2 \longrightarrow ZnCl_2$;
12) $Fe + 1\frac{1}{2}\,Cl_2 \longrightarrow FeCl_3$

The great economic advantage of the Miller process, in addition to low production costs, lies in the fact that the gold leaves the refinery in a marketable form, thus minimizing the financial losses due to tying up of the metal. To meet requirements for higher purities, Wohlwill Electrolysis may follow in addition.

5.3. Wohlwill Electrolysis [27], [72], [73]

The Wohlwill electrolytic refining process for gold was developed in 1878 at the Norddeutsche Affinerie in Hamburg. It is still indispensable for the industrial production of fine gold of quality $\geq 99.9\,\%$ (in practice usually 99.95 % and 99.99 %).

The Wohlwill process uses an electrolyte containing 2.5 mol/L of hydrochloric acid and 2 mol/L of tetrachloroauric acid. Electrolysis is carried out with agitation at 65 – 75 °C. The raw gold is introduced as cast anode plates. The cathodes, on which the pure gold is deposited, were for many years made of fine gold of thickness 0.25 mm. These have now largely been replaced by sheet titanium or tantalum cathodes, from which the thick layer of fine gold can be peeled off. In a typical electrolysis cell (Fig. 6), gold anodes weighing 12 kg and having dimensions $280 \times 230 \times 12$ mm are used. Opposite them are conductively connected cathode plates, arranged two or three on a support rail. One cell normally contains five or six cathode units and four or five anodes. The maximum cell voltage is 1.5 V and the maximum anodic current density 1500 A/m^2. At the anode, the reaction

Figure 6. Wohlwill electrolysis cell

$$Au + 4\,Cl^- \longrightarrow [AuCl_4]^- + 3\,e^-$$

takes place, and at the cathode the reverse reaction. Some of the gold dissolves anodically as gold(I)

$$Au + 2\,Cl^- \longrightarrow [AuCl_2]^- + e^-$$

Anodes and cathodes are normally replaced every two days. About 10 % of the anode gold, especially parts located above the electrolyte, is remelted to form new anodes. The anode slime is collected in a trough in the bath. In addition to silver chloride, it contains rhodium, iridium, ruthenium, and osmium, which can be recovered, and approximately 10 % of the anode gold formed by the reaction

$$3\,AuCl + HCl \longrightarrow 2\,Au + H[AuCl_4]$$

Platinum and palladium can be recovered from the electrolyte, which also contains copper, iron, and nickel.

The accumulation of metallic impurities in the electrolyte, and of anode slime in the cell, means that the electrolyte can only be used for a limited period of time. Therefore, the material to be refined should have a high gold content (generally > 95 %) and it is often best to use gold which has already been through the Miller process. Especially the silver content should not be too high to avoid passivation of the anodes by formation of insoluble chloride films. The gold quality of the cathode deposits depends on the condition of the electrolyte, and on the amount of anode slime that has collected in the cell. A purity of 99.9 % is considered to be a minimum, which is the quality of Russian commercial gold. Today, 99.99 % can be considered as the norm, rather than 99.95 %. Sometimes anode bags are used to increase the purity of the gold.

The great advantage of the Wohlwill electrolysis process is the high purity of the gold produced. In addition, the byproducts, especially platinum-group metals, are also relatively easy to isolate. A disadvantage is the fairly long period during which the noble metal is tied up, leading to considerable financial losses.

World capacities for Wohlwill electrolysis are very large. In the Republic of South Africa, approximately a quarter of all gold from primary production, after it has gone through the Miller process, undergoes final purification to fine gold by Wohlwill electrolysis. In the Soviet Union, all gold is treated by electrolysis, as it normally contains platinum-group metals. Practically all noble-metal parting works which recover gold from secondary materials are dependent on electrolytic refining, again because platinum-group metals are normally present. Today, almost exclusively fine gold (99.99 %) is used, both for industrial purposes, and for investment; trading countries such as Switzerland therefore have large refining capacities, mainly producing gold of a quality between "good delivery" (99.5 %) and 99.99 %.

Chemical reactions (see Section 5.1) for the refining of gold have both advantages and disadvantages in comparison to electrochemical reactions. While Wohlwill electrolysis has low operating costs, it needs a high hold up of gold as electrolyte and residual anode. The chemical reactions can be used for different kinds of gold-containing input material and are carried out in multipurpose vessels. However, the demand for chemicals and the amount of off-gas produced are higher.

5.4. Solvent Extraction [74], [75]

Tetrachloroauric(III) acid can be extracted from aqueous solution by many organic solvents. Solvents which can form metal complexes (e.g., ethers and esters) are most effective. Total separation from the usual accompanying elements cannot, however, be achieved.

With the exception of dibutyl carbitol, no systems have yet been discovered which can be applied commercially. Yet a system with a high degree of separation efficiency and simple process management, including stripping the pure gold, could offer considerable advantages over currently used methods, even concerning the absence of a gold stock.

6. Recovery of Gold from Secondary Materials [1], [3], [20], [27], [35], [46], [47], [76–81]

6.1. Recovery from Gold Alloys

For the recovery of gold from alloys with a gold content of more than 30 %, the Miller process (see Section 5.2) is the most economical method. This also applies to the treatment of anode slimes from the electrolytic refining of silver (→ Silver, Silver Compounds and Silver Alloys), providing these have a high gold content and can be melted.

For small quantities of *gold-rich alloys,* a useful treatment is dissolution in hot aqua regia, or

in hydrochloric acid (usually at 20 – 50 °C) containing a halogen or hydrogen peroxide. Silver precipitates as sparingly soluble silver chloride. Relatively pure gold is recovered from the solution by selective reduction. If copper and lead ions are present, the best reducing agents are sulfur dioxide or hydrazine; if platinum-group metals are present, oxalic acid is used.

In the case of *gold – copper alloys,* which also may contain silver and nickel, treatment with aerated dilute sulfuric acid allows the separation of noble metals from base metals. Gold can only be separated from base metals in this way if the gold content of the alloy is less than ca. 65 %, and the material has been finely milled or powdered.

There are two historically important processes for treating *gold – silver* or *gold – silver – copper alloys*. The silver may be dissolved with nitric acid, preferably after realloying to a silver to gold ratio or a silver and copper to gold ratio of 3 : 1 (inquartation); or hot concentrated sulfuric acid can be used (affination). The latter process is rarely used today. Silver – copper alloys with a low gold content are not suited to the above process, but can be treated in noble-metal works by the lead cupellation process (see Section 6.2). Lead is removed as litharge, PbO, which also takes up copper as CuO, and other metal and metalloid oxides, leaving behind doré silver. This is subjected to electrolytic refining (→ Silver, Silver Compounds and Silver Alloys); gold collects in the anode slime.

6.2. Recovery from Sweeps

The noble-metal processing industry produces large amounts of waste dust and debris, known as sweeps (e.g., slag, ash, soot, precipitation and emulsion residues, and sweepings). The gold content of these materials is mostly in the range 0.5 – 10 %. Usually they are first carefully ground, screened, and, if necessary, dried or burned. The fine nonmetallic fraction and the coarse metallic fraction, which can usually be melted, are analyzed separately.

The usual method for treating gold-containing sweeps is to melt the material down, together with silver-containing sweeps, in a lead shaft furnace. Depending on the composition of the sweeps, calcium carbonate, silicic acid, lead oxide, carbon, and materials containing sulfur are added. The mixture of powdered components is normally briquetted, pelletized, or sintered before being fed into the shaft furnace. The metallic phase (alloy) produced in the furnace contains lead and almost all of the noble metal. This alloy is then converted to doré silver (a few percent Au; < 0.1 % Pb; the balance is Ag) in a cupel furnace (→ Silver, Silver Compounds and Silver Alloys) by oxidizing lead to lead(II) oxide. The silicate slag from the shaft furnace contains a negligible quantity of noble metal, and can usually be discarded. The slagging process may have to be repeated, for example if the noble-metal content exceeds 300 ppm. In the sulfidic phase, which forms between the metallic phase and the slag, almost all the copper collects with the nickel to form copper matte. The relatively high content of silver and valuable nonferrous heavy metals in the copper matte makes special treatment necessary; this is usually carried out at copper smelting works.

When raw gold is refined (see Chap. 5), the resulting residues contain more gold than silver. These substances are treated in a shaft furnace and then in a refining furnace, together with raw silver from the Miller process. Unlike other pyrometallurgical recycling methods for silver and gold, a copper matte phase is not formed in the shaft furnace. The Au : Ag ratio is normally 1 : 4.

6.3. Recovery from Surface-Coated Materials

Surface coatings containing gold come mainly from the electronics industry, plus a small proportion from the jewelry industry and electrical engineering. The base material is essentially metallic; the gold coatings are often only a few micrometers thick, but may account for a gold content between a few tenths percent and a few percent.

The most economic solution is usually to remove only the gold coating, and to send the underlying base material directly to a recycling process. Mechanical pretreatment is often required to expose the gold surface. Depending on the particular combination of materials and the degree and type of finishing employed, this can be carried out with a shredder, jaw crusher,

or edge runner. Frequently, this is followed by air separation, gravity separation, or magnetic separation to remove the ballast materials. It is normally not advisable to burn off plastic materials because the gold diffuses into the metallic base, and it is then impossible to remove it all. For this reason it is preferable to decompose the plastic material by pyrolysis.

To remove the gold from the metallic base, the material is usually agitated in alkaline cyanide solutions (10 – 20 g/L NaCN). Air is only rarely used as an oxidizing agent, because of the relatively low rate of dissolution. Instead, water-soluble aromatic nitro compounds (e.g., nitrobenzoic acid or nitrobenzenesulfonic acid) are normally employed. Potassium peroxodisulfate and hydrogen peroxide are also suitable, but they have a greater tendency to oxidize the cyanide ion. The base materials (e.g., iron, nickel, and cobalt) are attacked only to a limited extent during the dissolution process. When the base material is composed of copper, or a copper-rich alloy, zinc cyanide or lead salts are usually added as inhibitors to keep them from being attacked.

The gold is recovered from cyanide solution by adding zinc powder (see Section 4.3), after any excess oxidizing agent has been reduced with hydrazine or formaldehyde. The gold can also be recovered by electrolysis, using insoluble graphite or magnetite anodes (100 A/m^2 cathode, 3 – 4 V), or platinized titanium anodes. Excess oxidizing agent should also be reduced to obtain optimum current efficiency and speed of deposition. In addition to the reductive deposition of gold, thermal decomposition of the dicyanoaurate(I) complex is also possible.

Gold-plated metallic wastes can also be directly deplated by electrolysis, preferably in electroplating drums used as anodes. The gold is recovered in metallic form from the cathode in a single step. The method is, however, not very well suited to the recovery of gold from bulk material in anode baskets, because the electric field is screened off from the material at the center of the load, and as a result not all the gold is removed.

Gold can be extracted from solutions with a very low gold content (≤ 0.1 g/L) by anion-exchange resins (e.g., Lewatit M 500) [80] or activated charcoal [81]. However, elution is costly and usually incomplete; the gold-loaded carriers are therefore most frequently ashed, and the gold recovered from the ash. The solutions are not returned to the deplating process because they contain degradation products, especially from organic nitro compounds, which would interfere with the process.

The methods described above can also be used to treat other cyanide gold solutions, e.g., unusable electroplating baths.

Gold-plated materials are occasionally smelted together with copper ores in large copper-smelting works. In addition to silver, these ores always contain some gold. A disadvantage of this method is the long time the gold has to stay in the process. Gold collects in the anode slimes during electrolytic refining of the copper and can be recovered from these. All gold concentrates recovered using the processes described here still require refining (see Chap. 5).

7. Gold Compounds [1], [12], [20], [38], [45], [70], [82–86]

Almost all gold compounds occur in the oxidation states +1 and +3. The oxidation states +2 and +5 are also known. Bimetallic compounds of gold(II) are usually mixed valence compounds containing gold(I) and gold(III).

The generally very low stability of binary gold(I) and gold(III) compounds based on ionic bonding can be ascribed to the structure of the two outer electron shells. The ten electrons of the $5d$ level and the single electron of the $6s$ level differ only slightly in energy. Therefore, ionization of the $6s^1$ electron to leave a $5s^2p^6d^{10}$ valence shell, i.e., the reaction $Au \rightarrow Au^+$, is energetically not particularly favorable. Gold(III) compounds with the $5s^2p^6d^8$ valence shell exhibit a tendency to fill the $5d$ level. Thus, the electron-acceptor effect is strong, and the compounds are strong oxidizing agents. The simultaneous participation of both outer electron shells gives rise to properties characteristic of the transition metals, such as variable oxidation state, colored compounds, and the tendency to form complexes.

7.1. Potassium Dicyanoaurate(I)

Properties. Potassium dicyanoaurate(I) [*13967-50-5*], $K[Au(CN)_2]$, M_r 288.10, d

3.452 g/cm^3, forms colorless crystals which are readily soluble in water and alcohol, but insoluble in acetone and ether. The solubility in water is strongly dependent on the temperature (Fig. 7). The effect of potassium cyanide concentration on the solubility of potassium dicyanoaurate is shown in Figure 8. The complex is neither air nor light sensitive and is stable in aqueous solution above pH 3.

Figure 7. Solubility of potassium dicyanoaurate(I) in water as a function of temperature

Preparation [70], [87]**.** Potassium dicyanoaurate is prepared from fulminating gold, from gold(III) hydroxide, and by electrolysis. The third method is now the most common preparation from fulminating gold is potentially hazardous.

From Fulminating Gold. Fulminating gold is precipitated from a solution of tetrachloroauric(III) acid by addition of excess aqueous ammonia; the precise composition of the precipitate is not known. The chloride content of the precipitate decreases with increasing excess of ammonia.

Fulminating gold must not be allowed to dry, since it is highly explosive in this state. The fulminating gold must be thoroughly washed with deionized water to remove chloride, since chloride ions interfere in electroplating processes. After washing, the precipitate is dissolved in a small excess of potassium cyanide solution. This is followed by filtration, concentration, and crystallization. The mother liquor is repeatedly reused in the process.

Electrolysis. When a gold anode is dissolved in aqueous potassium cyanide, potassium dicyanoaurate(I) is formed with hydrogen being liberated at the cathode. To prevent the dicyanoaurate(I) ion from being electrolyzed at the cathode with deposition of gold, a diaphragm is used. Fluoropolymer-based ion-exchange membranes are used for this purpose. The mother liquor is reused or worked up following crystallization of the potassium dicyanoaurate(I). This can be carried out under particularly mild conditions by using the continuously-cooled crystallization process. Cyanide and chloride are the major impurities. Electrolysis produces potassium dicyanoaurate(I) with a particularly low chloride content, which depends solely on the quality of the potassium cyanide and of the water.

From Gold(III) Hydroxide. Instead of fulminating gold, gold(III) hydroxide may be reacted with potassium cyanide solution. Precipitation of gold(III) hydroxide from tetrachloroauric(III) acid by addition of an alkali metal hydroxide does not always go to completion. Aging of the gold(III) hydroxide considerably reduces its rate of dissolution in potassium cyanide solution.

Uses and Economic Aspects. Potassium dicyanoaurate(I) serves as the gold component in the baths commonly used for electroplating and to a lesser extent in electroless plating (→ Electrochemical and Chemical Deposition, Chap. 8.9.). Plating baths with higher acidity are based on tetracyanoaurate (III) [88].

With increasing utilization of gold-plated electronic components, the demand for gold plating baths, and hence for potassium dicyanoaurate(I), has grown considerably. In 1997

ca. 6 % of the 3890 t of gold processed annually in the world was used by the electronics industry. In the jewelry industry, too, that demand has increased as a result of rolled gold being superseded by electroplating with hard gold.

Figure 8. Dependence of the solubility of potassium dicyanoaurate(I) in water upon the concentration of potassium cyanide at 20 °C and at 0 °C

7.2. Tetrachloroauric(III) Acid

Properties. Tetrachloroauric(III) acid [*16903-35-8*], $H[AuCl_4]$, M_r 411.85, crystallizes as a tetrahydrate in the form of light yellow, deliquescent crystals. It is readily soluble in water, soluble in alcohol and ether, and is corrosive.

Preparation [70]**.** Tetrachloroauric acid is prepared by dissolving gold in warm aqua regia. In order to remove residual nitric acid, the solution is concentrated by evaporation with repeated addition of hydrochloric acid, and the resulting melt is poured into porcelain dishes. Moisture must be excluded while the melt cools, solidifies, and is finally powdered. Crystallization from the aqueous mother liquor produces an extremely hygroscopic material. Instead of nitric acid, other oxidants (e.g., chlorine) may be added to the hydrochloric acid. The high rate of dissolution of aqua regia is only rarely attained (see Fig. 2), but the pollution caused by it is lower and control of the reaction is simpler, especially under industrial conditions. Care must be taken to assure removal of any excess oxidants and their reaction products. Tetrachloroauric(III) acid can also be prepared by anodic dissolution of gold in hydrochloric acid, but this requires the use of a diaphragm.

Uses [1]**.** Tetrachloroauric(III) acid is used to prepare other gold compounds. It is also used to make gold ruby glass, gold purple (Purple of Cassius), and purple colorants for enameling of ceramics (→ Ceramic Colorants) and to prepare the electrolyte for the Wohlwill electrolysis.

7.3. Sodium Disulfitoaurate(I)

Properties. Sodium disulfitoaurate(I) [*39394-92-8*], $Na_3Au(SO_3)_2$ M_r 426.06, is relatively unstable in the solid state, and is therefore not isolated as crystals for industrial use. It is stable in weakly alkaline solutions above pH 8.5, even upon heating and when exposed to light.

Preparation. Sodium disulfitoaurate(I) is prepared from fulminating gold or from gold(III) hydroxide.

From Fulminating Gold. Fulminating gold (see Section 7.1) is dissolved with stirring in a dilute solution of sodium hydrogen carbonate; sodium sulfite is then added. The reaction mixture is stirred at 70 °C until it clears. The pH must be maintained above 9. This is achieved by addition of sodium hydrogen carbonate solution. In order to remove ammonia, the solution is heated to about 90 °C with the simultaneous introduction of air. The gold content of the solution is kept at ca. 100 g/L by evaporation or by dilution with deionized water. This concentration is desirable for electroplating purposes. Instead of sodium sulfite, gaseous sulfur dioxide and a correspondingly higher quantity of sodium hydroxide solution may be used; the pH is controlled as described above.

From Gold(III) Hydroxide. Instead of fulminating gold, gold(III) hydroxide may be used. The reaction takes place under approximately the same conditions as with fulminating gold. The disadvantages are the same as in the preparation of potassium dicyanoaurate(I) from gold(III) hydroxide (see Section 7.1).

Uses. Sodium disulfitoaurate(I) is sometimes used in preference to potassium dicyanoaurate(I) in electroplating baths. These baths are especially advantageous for the production of ductile and wear-resistant coatings and in white-gold and rose-gold electroplating. Their disadvantages are difficult handling, shorter service life, and higher price. Their low toxicity is counterbalanced by problems in waste water disposal, e.g., those caused by the ethylenediaminetetraacetic acid (EDTA) complexes of the alloying elements.

Sodium disulfitoaurate(I) is increasingly being replaced by the corresponding ammonium salt, which provides special advantages with Au – Pd – Cu baths, such as the facility to produce very dense coatings.

7.4. Miscellaneous Gold Compounds [1], [20], [70], [89]

Bright gold preparations (gold sulforesinates) are used for gilding ceramics and glass (→ Ceramic Colorants). Other compounds, some of which have applications in preparative and analytical chemistry, include gold(III) chloride $AuCl_3$, gold(I) chloride AuCl, gold(III) hydroxide $Au(OH)_3$ or AuO(OH), gold(III) oxide Au_2O_3, the gold sulfides Au_2S, AuS, and Au_2S_3, gold(I) cyanide AuCN (→ Cyano compounds, Inorganic, Chap. 2.3.4.), and gold(I) acetylide Au_2C_2. Sodium dithiosulfatoaurate(I), $Na_3[Au(S_2O_3)_2] \cdot 2\,H_2O$, is used as a photographic sensitizer, and gold(III) selenate, $Au_2(SeO_4)$, for staining glass.

([90], [91]): Gold compounds, particularly gold thiosulfate, gold mercaptides, and gold malate, have long been used for the treatment of rheumatic disease (→ Anti-inflammatory – Antirheumatic Drugs, Chap. 4.1.). The triethylphosphine gold complex of thioglucose tetraacetate, Auranofin [*34031-32-8*], is very effective against chronic inflammation of joints. Gold(I) complexes of diphosphines may be beneficial in tumor therapy. Gold(I) and gold(II) complexes have antimicrobial activity.

8. Gold Alloys [1], [12], [20], [28], [35], [45], [92–103]

Because of its mechanical softness, gold is, like most other noble metals, used in elemental, unalloyed form only in special functions in electronics, sensors, optical devices, and catalysts. For the majority of applications, gold must be alloyed to adjust its mechanical (strengthening), thermal, physical (electrical, color), and structural (grain refining) properties according to special requirements.

The practical uses of gold alloys and of fine gold are mainly determined by their color, hardness, corrosion resistance, melting point, and relative value. The degree of hardness can be controlled by heat treatment. The melting point plays a significant role during manufacture and processing.

Structure Types. Gold forms numerous alloys and intermetallic compounds with many metals and metalloids. The alloys have in most cases face-centered cubic (fcc), hexagonal close packed (hcp), or body centered cubic (bcc) crystal structures, but there are also a great variety of different structure types, especially for the intermetallic compounds. Gold forms continuous solid solutions with the fcc-crystallizing

metals silver (atomic radius 144.5 pm), copper (127.8 pm), platinum (137.3 pm), palladium (137.6 pm), iron (124.1 pm), cobalt (125.3 pm), and nickel (124.6 pm). The solid solutions are generally of the substitutional type, where the solute atoms replace atoms of the solvent atoms in their lattice positions. Substitutional solid solutions are only formed if the components have the same or similar crystal structures and if the atomic radii of solute and solvent do not differ by more than ca. 15 % ("size factor" after HUME-ROTHERY [104]).

Figure 9. Solid solution hardening of gold [110]

Some systems show miscibility gaps, which in combination with temperature-dependent decreasing mutual solubility are used for precipitation hardening.

Alloying with elements with other lattice structures or larger differences in atomic radii like the hexagonal-crystallizing metals zinc (atomic radius 133.5 pm), cadmium (148.9 pm), or mercury (150.3 pm) results in the formation of more complex structures.

In some of these alloy systems, structural ordering reactions occur with the formation of superlattices of the same or similar lattice types. Such transformations are accompanied by changes in the mechanical and physical properties which find application in the hardening of the corresponding gold alloys. Superlattices, formed by disorder – order reactions are found in gold alloys with components which show marked differences to gold in their electrochemical properties or in their atomic sizes. Typical compositions have atomic ratios between 3 : 1 and 1 : 3, or 2 : 1 and 1 : 1 (e.g., Au3Cu, AuCu3, Au3Pd, Au3Cd, Au3Zn, Au2Mn, AuCu, AuMn) [105, p. 636]. The ordered phases form in certain temperature ranges superstructures with alternating regular linear arrangement of periods of definite lengths, which meet in the crystal at the so-called anti-phase boundaries (APBs). The number of cells per period depends on the valence-electron concentration and changes with alloying element and composition [106].

Figure 10. Influence of alloying elements on the electrical conductivity of gold [112]

Intermetallic compounds of gold with metals of the A group and with the B group elements of the periodic table form a variety of different structures in dependence on the alloying elements and the composition. Many of them are stable over an extended composition range and represent metallic phases rather than intermetallic compounds of definite stoichiometric composition [107], [108].

Intermetallic compounds with B metals form identical or similar crystal structures at electron – to – atom ratios of 3/2, 21/13, and 7/4

Table 2. Hume-Rothery phases of Cu, Ag, Au

Electron: atom ratio = 3 : 2			Electron: atom ratio = 21 : 13	Electron: atom ratio = 7 : 4
Body-centered cubic structure	Complex cubic ("β-manganese") structure	Close-packed hexagonal structure	"γ-brass" structure	Close-packed hexagonal structure
CuBe	Cu_5Si	Cu_3Ga	Cu_5Zn_8	$CuZn_3$

AuZn			Au_5Cd_8	
AuCd			Au_9In_4	

(Hume-Rothery phases) [97, p. 197]. Table 2 gives some examples.

Besides these, there are a huge number of other intermetallic phases with predominantly cubic, hexagonal, or tetragonal symmetry [36, p. 502].

Influence of Alloying. Strengthening is performed by alloying and by thermal treatment. Hardening is effected either by solid solution (causing elastic interactions between dislocations and solute atoms), by precipitation hardening using miscibility gaps, or by dispersion hardening [109]. Figure 9 gives some examples for the solution hardening effect of different alloying elements [110]. Precipitation hardening is of practical importance in jewelry, in dentistry, and in industrial apparatus and construction components. In binary and ternary gold – copper and gold – copper – silver alloys with higher copper contents, additional hardening can be obtained by means of ordering reactions [111]. Dispersion hardening is effected by incorporating in very fine distribution small amounts (0.1 – 2 vol %) of very small particles of high-melting compounds (e.g., oxides, carbides), which are insoluble or only become soluble near the melting temperature of the noble metal matrix. Dispersion strengthening is of importance if high electrical conductivity has to be combined with high-temperature mechanical strength and corrosion resistance. Dispersion-hardened alloys are produced by powder-metallurgical methods, supported by milling of the mixed powders (mechanical alloying), by internal oxidation of the base metal components in the alloy, or by precipitation of the gold powder in the presence of refractory oxides.

Fine grain structure is needed for reasons of higher strength and forming characteristic to give a smooth surface, especially in jewelry and dentistry. Effective grain refining for castings of gold and gold alloys is performed by adding small amounts of iridium, ruthenium, rhenium, zirconium, barium, tantalum, niobium (0.01 – 0.1 %), or combinations of Co/Ba, Co/Mo, Ni/Mo. Zirconium, barium, and cobalt increase the recrystallization temperature by about 150 – 200 °C and suppress grain growth on further annealing.

Figure 10 shows the influence of alloying additions on the electrical conductivity [112]. The increase in resistivity in the low concentration range is proportional to the atomic concentration of the solute.

8.1. Binary Alloys [28], [98–102], [113]

The phase diagrams of some important binary gold alloys are shown in Figures 11, 12, 13, 14, 15, 16, 17, 18, 19. The most frequently used binary alloys of gold are:

Figure 11. Phase diagrams of groups 1 and 2 binary gold alloys (upper abscissas in wt %, lower abscissas in atom %)

Figure 12. Phase diagrams of groups 4 to 6 binary gold alloys (upper abscissas in wt %, lower abscissas in atom %)

Gold – Silver. Gold forms a continuous series of mixed crystals with silver, without any transition or separation in the solid state. Au – Ag 20 is used for low-voltage electrical contacts, e.g., rivets.

Gold – Copper. Gold – copper alloys solidify as a continuous series of mixed crystals, with a melting point minimum at 910 °C and ca. 20 wt % copper. Below 400 °C, the ordered phases Cu_3Au [*60748-60-9*], CuAu [*12006-51-8*], and $CuAu_3$ [*12044-96-1*] appear in the solid state. Au – Cu alloys are also used as highly oxidation resistant, high-temperature stability alloys in turbines, nuclear, and space technology, and jet engine components.

Gold – Nickel. This continuous series of mixed crystals, with a melting point minimum at 950 °C and ca. 18 wt % nickel, decomposes at temperatures below 800 °C into gold-rich and nickel-rich mixed crystals. These alloys are used

Figure 13. Phase diagrams of groups 9 and 10 binary gold alloys (upper abscissas in wt %, lower abscissas in atom %)

Figure 14. Phase diagrams of groups 8 to 10 binary gold alloys (upper abscissas in wt %, lower abscissas in atom %)

Figure 15. Phase diagrams of group II binary gold alloys (upper abscissas in wt %, lower abscissas in atom %)

as brazing alloys; the most common composition is Au – Ni18 wt %. It has high oxidation resistance and good thermal stability up to 800 °C. The production of turbines, jet engines, and components and devices in nuclear and space technology are fields of application. Au – Co5 and Au – Ag26 – Ni3 serve as contact materials which are resistant to silver migration.

Au alloys with small amounts (up to 1 – 3 wt %) of iron, cobalt, or nickel are electrolytically deposited as hard, wear-resistant surface coatings of electrical contacts.

Gold – Palladium. With palladium, gold forms a continuous series of mixed crystals, without any phase separation in the solid state.

Gold – Platinum. Gold mixes with platinum in all proportions. Unlike the narrow melting range in gold – palladium alloys, most gold – platinum alloys solidify within a very

Figure 16. Phase diagrams of group 12 binary gold alloys (upper abscissas in wt %, lower abscissas in atom %)

Figure 17. Phase diagrams of group 13 binary gold alloys (upper abscissas in wt %, lower abscissas in atom %)

broad temperature range. In the solid state, a miscibility gap develops, which approaches the solidus curve in the middle of the phase diagram. Because of their high corrosion resistance, Au – Pt alloys are used for spinnerets in rayon production, and also serve as high-melting platinum solder. A typical composition is Au – Pt30 with a liquidus temperature of 1450 °C and a solidus temperature of 1228 °C. Alloys with 40 – 65 wt % Au can be effectively hardened by quenching from 1100 °C and annealing at ca. 500 °C to a tensile strength at room temperature up to ca. 1400 N/mm^2. Au – Pt10 and Au – Ag25 – Pt5 are used for electrical contacts operating under highly corrosive conditions. Au – Cu14 – Pt9 – Ag4 is used for oxide-free slip contacts of high reliability at very low voltage and current.

Figure 18. Phase diagrams of group 14 binary gold alloys (upper abscissas in wt %, lower abscissas in atom %)

Figure 19. Phase diagrams of group 15 binary gold alloys (upper abscissas in wt %, lower abscissas in atom %)

Gold – Zinc. With zinc, gold forms mixed crystals to a limited extent. The phase diagram for this system is very complex, and shows a large number of intermetallic phases and transitions in the solid state.

Gold – Cadmium. The characteristics of this system are very similar to those of gold – zinc.

Gold – Titanium. The alloy Au – Ti1 wt % has become important in the field of bonding wire for the connection of bond pads of semiconductor chips of intergrated circuits to the outer leads. Thermomechanical treatment effects strengthening by forming the intermetallic compound Au4Ti. Additional hardening can be performed by dispersion hardening by prolonged heating at elevated temperatures in air, which effects the formation of finely dispersed titanium oxide particles by internal oxidation of the titanium containing component [114].

Au – Si, Au – Ge, Au – Sn. The alloy systems gold – silicon, gold – germanium, and gold – tin form low-melting eutectics (AuSi3, 1 wt %: *mp* 370 °C, AuGe 12 wt %: *mp* 356 °C, AuSn 20 wt %: *mp* 280 °C). They are of high strength and serve as corrosion resistant and mechanically stable solders in the fabrication of semiconductor devices.

Gold – Mercury. Up to a gold content of ca. 10 %, these alloys are liquid at room temperature. For higher gold contents, many intermetallic compounds occur. Room temperature is usually sufficient for the formation of gold amalgams, which are still used in the recovery of gold.

The phase diagrams for most of the remaining systems, including those which are not used in industry, have also been thoroughly investigated.

Figure 20. Gradation of color of gold – silver – copper alloys

8.2. Ternary Alloys [103]

For centuries, the color (Fig. 20), hardness (Fig. 21), and corrosion resistance (Fig. 22) of gold were modified by variations in the Au – Ag – Cu system. When white gold, with its resemblance to platinum, became fashionable at the beginning of this century, Ni and Pd were added; these were soon followed by Zn, and later by platinum. The gold alloys used for modern dental materials are complex because they must have specific properties.

The ternary alloys of gold are industrially more important than the binary alloys and have been thoroughly investigated and documented.

Figure 21. Brinell hardness of annealed and quenched gold – silver – copper alloys

Figure 22. Corrosion resistance of gold – silver – copper alloys
a) Alloys are tarnish resistant and resist all acids except hydrochloric acid in the presence of an oxidizing agent; b) Acids may dissolve out copper and silver from the surface of the alloy; c) Alloys tarnish and are attacked by acids

Gold – Silver – Copper. Figure 23 shows the liquidus, and Figure 24 shows isothermal sections through the miscibility gap of the gold – silver – copper system. The melting surface is characterized by a gutter starting from the

silver – copper eutectic and continuing in the direction of the melting point minimum of the gold – copper system. As the temperature decreases, the miscibility gap at the silver – copper binary edge broadens out considerably towards the gold corner. Shortly after solidification, the heterogeneous phase only extends to alloys containing slightly more than 40 % gold; at 400 °C, it includes alloys with 75 % gold.

Figure 23. Liquidus of the gold – silver – copper system

Figure 24. Isothermal sections through the miscibility gap of the Au – Ag – Cu system

The miscibility gap covers a large part of the gold – silver – copper system, and its extent is strongly dependent on the temperature. This is of great significance in the processing and application of gold alloys, and is the main reason why age-hardening is possible.

Figure 25 shows a section through the phase diagram of the gold – silver – copper system, running from the gold corner to the middle of the silver – copper edge. As the temperature decreases, the regions in which mixed crystals and melt occur are followed by regions in which gold-rich α mixed crystals, and the two mixed crystals α_1 (silver-rich) and α_2 (copper-rich) coexist. The saturation line of the α mixed crystal, which separates the two regions from each other, is highly temperature dependent. At 750 °C, the α mixed crystal can dissolve ca. 50 % silver and copper (in approximately the ratio 1 : 1); at ca. 300 °C, it can only take up about 10 % silver and 10 % copper. An alloy with 70 % gold, which at high temperatures consists only of α mixed crystals, reaches the saturation line during cooling at ca. 480 °C. With further cooling, it splits into the α_1 and α_2 mixed crystals. At tempering temperatures below 480 °C, the alloy therefore age-hardens.

Figure 25. Section through the Au – Ag – Cu phase diagram running from the Au corner to the middle of the Ag – Cu edge

Figure 26 shows a section through the ternary system parallel to the silver – copper binary edge with a constant gold content of 70 %. The extensive region of the α mixed crystals adjoins the miscibility gap which ends just below 500 °C. In the miscibility gap region, the α_1 mixed crystal, which has a relatively high silver content, and the α_2 mixed crystal, which has a relatively high copper content, coexist.

Gold – Nickel – Copper. Figure 27 shows the liquidus isotherm of the gold – nickel – copper system, which produces white alloys over broad areas. Below 800 °C in the gold – nickel system (Fig. 14), a miscibility gap stretches far into the ternary system, as the temperature falls, in the direction of the copper corner. These alloys can therefore be age-hardened, but are not always easy to process, particularly as the nickel content makes them very sensitive to traces of sulfur. As little as 0.01 % sulfur is sufficient to make them brittle when hot. Phase separation in nickel-containing white gold alloys leads to the formation of a gold-rich mixed crystal, and a nickel-rich ferromagnetic phase, which tends to lower the chemical resistance of the alloys.

Figure 26. Section through the Au – Ag – Cu phase diagram parallel to the Ag – Cu edge with a constant gold content of 70 %

Gold – Silver – Palladium. Figure 28 shows the liquidus isotherms of this system, which produces white, high-melting alloys over a broad area. These are relatively soft and cannot be age-hardened.

8.3. Higher Alloys

In jewelry, the most important quaternary alloys are derived from the ternary systems Au – Ag – Cu, Au – Ni – Cu, and Au – Ag – Pd, most often through the addition of zinc. The Au – Pd – Ag – Cu and Au – Ni – Ag – Cu systems are also of practical importance. Colored gold solders may contain cadmium in addition to the above elements.

Dental gold alloys often have five or more components. These are formed from Au – Ag – Cu by addition of Pd and Pt.

Figure 27. Liquidus isotherms of the gold – nickel – copper system

8.4. Production and Processing [115–117]

Manufacture. Bars, rods, foils, and wires are manufactured by classical metallurgical processes: melting, casting, rolling, drawing, and powder-metallurgical compaction. Pure gold is very malleable. It can be rolled to very thin foils and drawn to wires of very small diameters. Special procedures have been developed for the production of gold leaf (see Section 10.9) and for casting small jewelry items. Gold powders of different grain sizes and shapes are made by precipitation from preferably aqueous solutions of gold compounds with reducing agents. Thicker, compact surface layers are produced by cladding, especially for electrical contact pieces

and jewelry items (Doublé). Thin surface layers or films are produced by galvanic processes, by application of gold-powder-containing paste preparations, by evaporation, or by sputtering. Metallizing pastes contain additions of organic vehicles for flow properties. They are applied by painting, by brushing or by screen printing, in the latter case usually followed by drying and firing. Special preparations differing in gold powder grades and type of liquid components are in use for the production of electronic devices. Pastes for the production of so-called thick-film layers on ceramic substrates may contain glass powders which effect in the firing operation bonding on the ceramic surface.

Figure 28. Liquidus isotherms of the gold – silver – palladium system

Melting. Gold alloys are made by melting fine metals in crucibles made of a clay – graphite mixture or fireclay. Gas-heated furnaces used to be common, but electrically heated smelting plants or induction furnaces are now used. In order to prevent oxidation of the base metal components, the melt is covered with lumps of charcoal and borax. The air above the crucible can also be replaced by carbon dioxide. Melting is sometimes carried out in vacuum. The molten metal is poured into preheated iron molds to obtain the required form.

Rolling and Drawing. Cast plates are flat rolled to form sheets; billets are first shaped on grooved rolls, and then drawn to form wires. Intermediate annealing processes are usually carried out in electrically heated furnaces. In order to prevent oxidation of gold alloys, a protective gas consisting of partially burned coal gas or propane is blown through the furnace.

Fabrication of Jewelry. In former times, gold jewelry was made by hand from sheets and wires, and the pieces soldered together. The mechanical properties of the alloys were not critical because the goldsmith was able to adapt his methods according to the material. With the increase in factory production, quality requirements became much more important. The correct choice of a gold alloy for a particular production process has thus become critical.

Beating, Deep-drawing, Spinning, and Pressing. Soft gold alloys are most suitable for these methods. Moderately hard or soft gold alloys are used to manufacture jewelry from sheet metal, such as brooches and rings. Chains and plaits are now almost exclusively machine-made; for this purpose, all soft alloys, and a very few moderately hard alloys can be used. Alloys for chains must have constant mechanical and processing properties, so that the machine can produce a well soldered strand. For pin shanks, spring catches, and other similar articles, the hardest possible alloys must be used, because good resistance to wear and high elasticity are required [117].

Punching. To make seamless wedding rings, a hole is punched out of a disk. The resulting piece then undergoes a heavy forming operation without removing any material, in a specially adapted production process.

Casting. The manufacture of jewelry by casting gold in molds made of metallic or inorganic materials, or sometimes organic materials (cuttlebone), has been used throughout history. The casting of jewelry using the lost wax process has become an important manufacturing method. Several wax models of the desired shape are made in a split mold, provided with a joint gate, and embedded in a paste mixed with water, consisting essentially of quartz and gypsum. When this paste has hardened, the wax is melted out, and the hollow mold fired at red heat. The molten gold alloy is then poured in. After cooling, the formed pieces are removed, smoothed, and polished.

Age-Hardening. The hardness of many gold – silver – copper alloys can be increased by heat treatment at 250 – 350 °C. However, in the fabrication of jewelry only limited use has been made of this possibility, because the hardening that takes place during forming is usually sufficient.

As age-hardening in gold – silver – copper alloys takes place at lower temperatures than recovery after cold forming, the superposition of age-hardening and forming operations can lead to a considerable increase in the hardness and strength of a workpiece. This method is useful in the fabrication of parts which are to serve as holding or fixing elements.

9. Quality Specifications and Analysis [20], [118–124]

9.1. Quality Specifications [39]

The gold content of fine gold and gold alloys is usually expressed in fineness (parts per thousand) or in carat, where 24 carat represent 1000/1000 (‰) fine, 18 carat thus being equal to 750/1000 (Table 3). For ores, intermediate industrial products, residues and waste materials, the gold content is usually given in gram per metric ton (g/t), µg/g, ounces per metric ton (oz/t) or ounces per short ton, where 1 oz = 1 troy ounce = 31.1035 g and 1 short ton = 907.184 kg. Other mass units are 1 dwt = 1 pennyweight = 0.05 oz = 1.555 g and 1 troy grain = 1/24 dwt = 0.0648 g. 1 tola = 11.664 g is an Indian mass unit for gold. The Chinese Gold and Silver Exchange Society uses the unit tael (1 tael = 37.429 g).

Gold bars are classified into two "qualities", depending on their method of manufacture: cast and struck. For the accredited refiners 38 different bar masses ranging from 12.5 kg to 1 g are recorded [125].

In international gold trading the content of gold is the decisive criterion. The concentrations of individual impurities are normally not taken into consideration if their sum does not exceed the specified upper limit. If agreed upon, the ASTM Standard Specification for Refined Gold (ASTM: B 562-95) can be used as a guideline for the chemical composition. Individual refiners may offer different specifications based on their own products. ISO 9202 lists the fineness of gold jewelry alloys, which constitute the mayor use of refined gold. Special industrial applications of gold may require particular specifications for individual metallic or nonmetallic trace elements.

9.2. Sampling [119], [126]

An essential part of any determination of the gold content of any material and of great economic significance is sampling before analysis. A number of partly automated standard sampling procedures are available for solid materials that can be homogenized by comminution and mixing (ores, concentrates, sweeps, and others), and for unrefined gold and gold alloys that can be homogenized by inductive melting. Where these approaches are not possible, homogenization by, for example, dilution melting with copper or other base metals may be necessary.

Grindable materials are usually screened after grinding to separate the fine from the (metallic) coarse fraction. These are then subjected separately to mechanical, electrothermal, or manual sampling processes.

In the case of metallic materials such as mined gold, doré silver, or industrial gold alloys, the material to be analyzed can be obtained by sawing sample bars or by drilling or sawing small dip samples (buttons).

For the sampling of jewelry alloys, an ISO procedure is being worked on at present [127].

Recycled electronic material contains mostly only a few parts per thousand gold together with plastic and base metal or ceramic components. In a multistage process, mechanical size reduction in a shredder in combination with fractionation by screening produces material from which samples can be taken [128].

9.3. Qualitative and Semiquantitative Analysis

For the determination of gold, a large number of spectroscopic methods, like FAAS, GFAAS, ICP-OES, and XRF is available. In emission and absorption spectroscopy the most sensitive lines at 242.8 nm and 267.6 nm are used. To detect gold in the µg/g range in powdered materials, fire assay with lead as collector (see Section 9.4) can

Table 3. Fine gold specifications

Designation	Gold content, wt %	Content of other metals, µg/g	
"Good delivery" gold	≥ 99.5	any metals (total)	≤ 5000
Fine gold	≥ 99.99	Ag	≤ 100
		Cu	≤ 20
		others	≤ 30
		total	≤ 100
Fine gold, chemically pure	≥ 99.995	Ag	≤ 25
		others	≤ 25
		total	≤ 50
Fine gold, high purity	≥ 99.999	Ag	≤ 3
		Fe	≤ 3
		Bi	≤ 2
		Al	≤ 0.5
		Cu	≤ 0.5
		Ni	≤ 0.5
		Pd + Pt	≤ 5.0
		total	≤ 10

be applied, in which silver nitrate, containing less than 1 ng/g gold, is added to the fluxing material, in order to improve the collector effect, and as protection against gold losses during cupellation. The resulting bead can be dissolved in nitric or sulfuric acid, gold traces collected on a membrane filter, dissolved in aqua regia, and semiquantitatively determined spectroanalytically. Occasionally, the formation of so-called purple of Cassius [124] is used as rapid industrial procedure for the semiquantitative detection of gold in tailing solutions from gold extraction.

9.4. Quantitative Analysis

Quantitative analysis forms the basis for calculating the gold content of all types of materials containing gold during its primary and secondary extraction. The first group includes, for instance, gold ores, concentrates, and mined gold, while the second represents recovery from scrap dental and jewelry alloys, doré silver, ion-exchange resins, spent galvanic baths, electronic scrap, and byproducts of the base metal industry, such as sludges from copper electrolysis, etc. Quantitative analysis is also used for quality control of the end products of refining ranging from commercial gold to ultrapure gold and all the products (e.g., alloys, and salts) obtained when gold products are processed.

The duality of the methods for analyzing gold for most of the materials mentioned is especially characteristic, that is, the parallel use of classical and modern instrumental methods. The most important analysis method for gold is still the centuries-old docimastic analysis or docimacy (Greek: testing, assay), more commonly known as the fire assay. In this process, precious metals are taken up by molten lead while base metals are removed by slagging. Two variations of the method are used to extract the gold from a mainly nonmetallic or base metal matrix. In the *crucible assay*, a mixture of lead oxide, a reducing agent (e.g. carbon), and a flux is melted at ca. 1300 °C. In the *scorification assay*, the sample is subjected to oxidative smelting with granulated lead and borax at ca. 1000 °C. In each case a lead button containing the gold and the other precious metals of the sample is formed.

The lead is then oxidized at ca. 900 °C to litharge (PbO) on a magnesia support known as a cupel (*cupellation process*). The PbO melt is absorbed by the porous magnesia (together with base-metal oxides possibly present) and a drop of precious metal(s), which later solidifies to a bead remains behind. The precious metal bead is treated with nitric acid. Depending on the silver/gold ratio in the sample material, it may be necessary to inquart the precious metal

bead with additional silver to facilitate quantitative separation of silver and gold during parting. If the precious metal bead consists of Au, Ag, Pt, and Pd in suitable concentration ranges, Ag, Pt, and Pd are dissolved with boiling nitric acid, while gold remains undissolved and can be weighed. Cupellation losses are compensated for by the use of proof samples of similar composition to the material being assayed.

If the precious metal bead contains rarer platinum group metals (Rh, Ir, Ru) in addition to gold then special decomposition techniques have to be applied.

An important alternative to the extraction of gold and other precious metals with lead is the use of copper as collector.

The cupellation of metallic samples, wrapped in lead with an addition of silver, is the most important method for the accurate determination of gold in alloys with ca. 30 to 99.9 % gold, e.g., dental alloys or mined gold [129]. The degree of accuracy of gold analysis of alloys by cupellation lies between about 0.1 ‰ and 1 ‰ depending on the gold concentration and the composition of the matrix.

Spectrometric methods with a precision much better than 1 % are acceptable as alternatives to fire assay for the accurate analysis of gold in the range from 0.1 % to the high-percentage region. Up to the late 1980s this was only true for wavelength and energy dispersive X-ray fluorescence analysis (XRF) of solid alloys or solutions, and to a limited extent for glow discharge optical emission spectrometry (GD-OES) of gold alloys [130], [131]. With the X-ray solution method as a multielement method for all precious metals except Ag, an accuracy of 1 ‰ can be achieved for the analysis of gold as main constituent [132], [133]. A small energy dispersive X-ray instrument [135] allows gold determinations in carat alloys with an accuracy of 2 to 3 ‰.

The basis for the precision analysis of precious metals by inductively coupled plasma optical emission spectrometry (ICP-OES) is internal standardization. The essential method characteristics for the determination of gold [134] are

- The use of a simultaneous spectrometer with high measurement stability
- The simultaneous measurement of the 267.6 nm or the 242.8 nm Au atomic line and the 371.0 nm ionic line of yttrium as internal standard
- The preparation of all solutions and the addition of the Y standard solution by exact weighing
- In special cases the use of a Na/Cu buffer, but in any case the use of a HCl concentration of at least 5 %.

Several wet chemical/gravimetric methods are used in special cases in conventional gold analysis, for instance, reduction of gold by SO_2 in hydrochloric acid solution.

9.5. Purity Analysis [121]

A large number of methods for purity analysis of gold are available; some of them can be applied to metallic gold, and others to the analysis of gold dissolved in acid.

9.5.1. Direct Analysis of Metallic Gold

1) Spark discharge emission spectrometry (SD-OES) with high-speed time resolution of individual sparks is well suited for the analysis of fine gold with total impurities in the range of 50 to 1000 µg/g, that is, for the most common grades of fine gold in routine operation; however, it is not suitable for 99.999 % gold.
2) DC arc spectrometry with simultaneous background correction offered by the application of a solid state detector (CID). The detection limits for all trace elements are lower than for spark excitation.
3) Spark ablation ICP-OES offers a further possibility of direct impurity analysis in which sample ablation is caused by high-voltage sparks and the resulting aerosol is transported into the ICP by an argon carrier gas stream.
4) Glow discharge emission (GD-OES) or ablation spectrometry (GDA-AAS). The detection limits for impurities in gold with classical DC-powered GD-OES are equal to or better than 1 µg/g.
5) Laser ablation ICP mass spectrometry can be applied to purity analysis in high purity gold with detection limits of better than 0.2 µg/g.

Table 4. Coinage alloys

Coin	Country	Mintage period	Fineness	Carat	Gross weight, g	Gold content
20 mark	German Reich	1871 – 1915	900	21.6	7.964	7.168 g
10 mark	German Reich	1871 – 1915	900	21.6	3.982	3.584 g
5 mark	German Reich	1871 – 1915	900	21.6	1.991	1.792 g
1 ducat	German Confederation	up to 1871	986.1	23.7	3.490	3.441 g
Krugerrand ∗	R. South Afr.	since 1967	916.6	22	33.931	1 oz
Maple Leaf ∗	Canada	since 1979	999.9	24	31.103	1 oz
American Eagle ∗	USA	since 1986	916.6	22	33.931	1 oz
Britannia ∗	Great Brit.	since 1987	916.6	22	33.931	1 oz
Nugget ∗	Australia	since 1987	999.9	24	31.103	1 oz
Tscherwonez	USSR	since 1975	900	21.6	8.60	7.74 g

∗ Also in 1/2, 1/4 and 1/10 oz gold.

It has also found an interesting application in the characterization of trace element composition of unrefined gold of different origins, akin to traditional fingerprinting. The method therefore facilitates identification of the provenance of stolen gold.

6) Glow discharge mass spectrometry GD-MS) is the queen among spectroscopic techniques for the analysis of gold of quality 99.995 % Au or better; it is used in the electronics industry.

9.5.2. Purity of Gold Solution

As an independent alternative method to direct metal analysis ICP-OES with a SIM/SEQU or sequence instrument with axial plasma can be used for production control or for the analysis of gold calibration standards. The use of an Au concentration of 50 g/L offers no difficulties. Especially advantageous is the use of ICP spectrometers with semiconductor detectors.

9.6. Trace Analysis

The determination of trace amounts of gold (ca. 0.1 – 100 µg/g) is important in ore prospecting and in the evaluation of residues and waste materials from the metallurgical industry.

The solids can be dissolved and the resulting solution analyzed by a suitable spectroscopic method:

- Flame atomic absorption (FAAS)
- Graphite furnace atomic absorption (GFAAS)
- X-ray fluorescence analysis with totally reflected exciting beam (TXRF)
- Direct current plasma optical emission spectrometry (DCP-OES)
- Inductively coupled plasma emission (ICP-OES)
- ICP quadrupole mass spectrometry (ICP-MS)

The gold traces may need to be enriched prior to determination to improve the detection limits, for instance, by solvent extraction. In the field of trace analysis, composite fire assay/atomic spectroscopy or mass spectrometric methods play an important role. They make use of the almost universal application of fire assay for the separation of gold and the possible of using large samples.

10. Uses of Gold and Gold Alloys [6], [12], [19], [20], [22], [35], [39], [45], [47], [136], [137]

10.1. Coins, Medals, and Bars [138]

In antiquity, gold was considered an object of value and used as a means of exchange, at first in the form of nuggets or flattened disks, and from 650 B.C. as minted coins. The composition of the metal used varied from alloys containing a high proportion of gold, to electrum which had a relatively high silver content. The confusing variety of gold coins, and the great variation in fine

gold content, was first limited in the 19th century, when legal regulations were introduced for coinage, which specified nominal values of gold coins, their weight, and gold content. After the First World War, gold coins were no longer legal tender. They are now traded as collectors' items and as a form of investment. With the liberalization of private gold trading in the 1950s, the demand for gold increased. A successful new enterprise in this market was the minting and marketing of the krugerrand (gold content of 1 oz troy) by the Republic of South Africa. Between 1967 and 1985, a total of 2000 t (ca. 65×10^6 oz.) were sold. Following the repressive measures which have been inflicted on the krugerrand, new coins were introduced by other countries (Table 4).

Gold was already stored in the form of bars in antiquity, especially in Rome. Today, gold bars weighing ca. 400 oz. (ca. 12 kg) of good delivery quality (99.5 %) are the main form used in public and institutional investment. Gross weight, gold content, the manufacturing firm and reference number are stamped on the bars, and provide direct and binding information as to their value. Smaller gold bars are manufactured for private investors.

The difference between the buying and selling price in banks (broker's commission) is normally ca. 3 – 4 % plus value added tax.

10.2. Jewelry [139]

Fine Content of Jewelry Gold. The gold value of jewelry alloys is determined by their gold content (fineness, cf. Section 9.1). In most countries, laws govern the terms used in designating the fineness of gold jewelry for manufacturers, processors, and dealers.

Only alloys with a minimum gold content of 585/000 are sufficiently tarnish resistant for jewelry. Better quality jewelry customarily has a gold content of 750/000. These alloys offer optimum color and mechanical properties. For less expensive jewelry, alloys with a low gold content are often used. In Germany, 333/000 fine is common, in other countries 375/000, and in the United States 417/000. These alloys tarnish under unfavorable conditions, and cracks may form as a result of stress corrosion. The highest grade alloys are used only occasionally in the manufacture of jewelry, due to their low strength. However, no alloy can match the fine color of pure gold.

Colored gold alloys used in the jewelry industry are mostly based on the ternary alloy system Au – Ag – Cu, Cu or the quaternary system Au – Ag – Cu – Zn allowing a wide variety of colors (see Fig. 20). The workability and resistance to wear of an alloy depend on its mechanical properties; these, its resistance to corrosion, and the color can be controlled by adding zinc. The classification ranges for colored gold alloys used in the jewelry sector are shown in Table 5. To designate the different qualities, special codes are used, most of which are specific to particular firms. The properties cover a broad range of values to meet all practical requirements (Tab. 6). In 1966 in the Federal Republic of Germany, an industrial standard, DIN 8238 "Gold colors" (including white gold), was created to standardize colors in gold alloys and to provide manufacturers with a better means of mutual understanding. This standard closely reflects similar specifications in Switzerland and France. A combination of values representing tone (T), saturation level (S), and darkness (D), measured using spectrophotometric methods, is attributed to each color (Tab. 7).

Table 5. Composition of gold alloys for jewelry

	Gold content, wt %	Content of alloy components, wt %
Colored gold		
22 carat	91.66	Ag 0 – 6.0, Cu 2 – 8.3
18 carat	75	Ag 0 – 20, Cu 5 – 25
14 carat	58.5	Ag 0 – 41.5, Cu 0 – 33.5, Zn 0 – 10
9 carat	37.5	Ag 0 – 56.0, Cu 4 – 60, Zn 0 – 15
8 carat	33.3	Ag 0 – 58.5, Cu 4 – 60, Zn 0 – 15
White gold		
18 carat	76	Cu 4 – 8, Ni 10 – 18, Zn 3 – 6
18 carat	75	Pd 10 – 20, Ag 0 – 1, rest Cu, Zn
14 carat	59	Cu 15 – 25, Ni 10 – 16, Zn 5 – 8
14 carat	59	Pd 10 – 20, Ag 10 – 30, rest Cu, Zn

Gold Solders. The most frequently used method of making joins in the manufacture of jewelry from gold alloys is hard soldering. In addition to fine gold, colored gold solders also contain silver, cadmium, copper, zinc, and indium. Their melting temperature is always lower than that of the material to be soldered. The additives are adjusted so that the solders have graduated

Table 6. Properties and applications of jewelry gold alloys (selection)

Carat	Destignation gold/silver, rest copper or (+Zn)	Color	Melting range, °C	Density g/cm^3	Vickers hardness (after soft annealing), HV 10	Applications

working temperatures. Three solders are generally sufficient, with graduations of ca. 50 °C in their working temperatures. Some examples of colored gold solders are given in Tables 8 and 9.

White gold alloys were first developed in the early 1900s, in an effort to replace platinum by a cheaper material with identical properties. White gold also differs from colored gold in having a higher melting range (white gold with palladium) and is usually harder (white gold with nickel). Nickel and palladium are the only suitable additives to give gold a color approaching whitish gray. Because of the allergic reaction of skin to Ni the demand for white gold has rapidly fallen. Information about white gold alloys is given in Table 5.

Table 8. Working temperatures of Cd-containing colored gold solders

10.3. Electronics and Electrical Engineering [22, pp. 475 – 500], [140], [141]

10.3.1. Electronics

The great advantage of gold is its high resistance to oxidation and corrosion, and its high conductivity which give it excellent contact properties.

It is therefore primarily used if oxide-free surfaces are indispensable. Gold surfaces enable the formation of electrical connections with lowest ohmic resistances, forming perfect electrical connections for solder, bond, and pressure contacts where even thinnest oxide layers would cause interruptions, formation of voids, and leakages. It is used in active components (diodes, transistors, integrated circuits, semiconductor memories), assembly and connection engineering (packages, thick-film circuits, printed boards, and plugs) and, to a lesser extent, for passive components (capacitors and resistors).

Table 10 gives a survey of the main application fields.

Partly due to its high intrinsic cost, it is mostly employed in the form of thin layers on different substrate materials.

The gold used in electronics, with the exception of gold solders, is practically always fine gold of purity 99.99 or 99.999 %.

The surface coats are deposited by electroplating [142], sputtering, evaporation, or by means of paste preparations, which are made from special gold powder grades and organic binders and – for adhesion on ceramic substrates – blended with glass frits. These are applied by screen printing and firing. They are especially used for conductor layers of hybrid thick-film circuits and ceramic devices. Gold conductor paths, pure or alloyed with silver, palladium, and platinum in thick-film circuits and in submicron-structure units can also be made by thermal decomposition by electron-beam lithography.

Gold-plated surfaces serve for connections by pressure, by bond – or solder – contacts on semiconductor chips and for the joining of the semiconductor pieces with assembling parts and package components [143]. Gold conducting layers are specially of importance in highly reliable electronic circuits, where silver conductor layers may cause problems by current-induced silver-ion migration.

Gold powder of different grain sizes with spherical or platelike grain shapes are used in metallizing and thick-film pastes to produce bond pads and conductor layers. Gold powder, as needed for paste preparations is produced by the chemical reduction of tetrachloroauric acid $H[AuCl_4]$. Depending on the type of reducing agent and the use of protecting organic colloids, either spherical particles (with sizes between 1 µm and 10 µm) or platelike particles (with

thickness of about 0.5 µm and flat dimensions of about 50 µm; see Fig. 29) are formed.

Thin wires ("bond wire", standard diameter 25 µm) made of pure gold, alloyed with small amounts (ca. 7 ppm) of beryllium serve for the connection of the majority of monolithic integrated semiconductor chips (I/Cs) with the inner leads of the device. Bonding is performed by special welding processes (thermocompression and thermosonic bonding), forming a bond loop between the connection pads and the outer leads of the device. The wire is fed through a heated capillary and the tip of the outcoming wire is melted to a small ball, which is pressed onto the semiconductor pad to form a weld contact (ball bonding or nailhead bonding, Fig. 30).

Bonding wire made of the alloy AuTi 1 has higher strength and higher mechanical stability at elevated temperatures. Strengthening is achieved by thermal treatment which causes the precipitation of the intermetallic compound $TiAu_4$. Additional dispersion hardening can be achieved by internal oxidation to form a finely dispersed titanium oxide phase in the alloy structure [114].

Gold-containing brazing and solder alloys are used for the joining of packaging and for the assembly of components. The eutectic alloys of gold with silicon, germanium, and tin (Table 11) are used for low-temperature solder connections with high mechanical strength. Gold and gold – silicon alloys are used to connect the semiconductor crystals with the base contact

Table 11. Low-melting gold solder alloys for electronic applications , p. 556[22]

Composition	Melting range, °C	Elongation, %	Thermal expansion, $10^{-6}\,K^{-1}$	Electrical resistivity, $\Omega\,mm^2\,m^{-1}$	Thermal conductivity, $W\,m^{-1}\,K^{-1}$

supports (die-attach) on lead frames, packages, or hybrid circuits.

Figure 30. Ball bonding of semiconductor chips with gold bond wire [36, p. 561]

Gold-plated metallic lids and solder preforms of the alloy AuSn20 are used for the hermetic (vacuum-tight) sealing of semiconductor device packages (Fig. 31) and for soldering of laser crystals. AuSn alloy connections are also formed by thermal bonding of Sn-plated leads onto Au bumps, placed on the surface of the semiconductor crystal with the tape-automated-bonding (TAB) technology [144]. AuSi alloys give solder bonds with the highest stability against thermal and mechanical stress and are therefore preferably applied in high-reliability semiconductor devices submitted to thermal cycling. AuGe12 and Au70In20Sn10 can be soldered at 400 – 500 °C. They are used for the soldering of Mo supports in power devices, packages, and components and leads of Cu and FeCoNi alloys.

Ternary solder alloys of AuAgGe, AgCuSn and AgCuIn of different compositions cover the temperature range of 400 – 650 °C. Some of these are brittle and must be applied in powder or paste form.

Figure 31. Flat pack ceramic package for integrated circuit devices with gold contact frame (with connections in dual inline array). Hermetic encapsulation by soldering of gold plated metal lid with AuSn20 solder frame.

Nanosized gold particles have potential applications in electronics, computing, sensors, and catalysis. On the nanometric scale, materials properties are strongly size dependent. Massive gold clusters, which consist of 1 – 2 nm sized gold cores encapsulated within a shell of tightly packed hydrocarbon chains have been prepared by decomposition of gold thiolate com-

pounds. The electromagnetic and conduction properties of these cluster molecules are extremely sensitive to charging and are of potential interest for use in microelectronic circuitry ("single electronics") [145–149]. Vapor-synthesis techniques have been used to prepare solvent-stabilized gold particles in the 1 – 3 nm regime. The clusters may provide active catalysts for the low-temperature oxidation of CO to CO_2 [150], [151]. Long "wires" of gold nano particles have been deposited along step edges of highly oriented pyrolytic graphite. The technique is supposed to perform in this way the connection between components in a nanoscale electrical circuit [152]. Spacing of nanoparticles of gold has been also performed by attaching single stranded DNA oligonucleotides of defined length and sequence to the nanoparticles [153], [154], [155].

10.3.2. Electrical Engineering [22, pp. 449 – 459]

Because of its high oxidation resistance, gold surfaces enable the formation of electrical connections with the lowest ohmic resistances. The surface layers are made by roll-bond cladding or electrodeposition. Gold and gold alloys are indispensable for conductor material and low-voltage contacts for communication and information transfer equipment, where even very thin oxide layers would cause interruptions or failures in signal transfer.

Gold – nickel and gold – silver alloys are used in weak-current engineering, as contact materials for very low voltage switches, and where the contact forces are low (relays, plugs, measuring instruments). Micromigration of these alloys is very low, and there is little tendency for insulating layers to form.

AuCr2 serves as resistor material in corrosive environments with stable temperature coefficient of resistance (TCR) between − 20 and + 40 °C.

Wires of multicomponents alloys based on gold and palladium serve as potentiometer windings in high precision techniques, where the lowest TCR values in particular temperature ranges are needed.

Gold-manganese alloys are used for wirewound resistance thermometers. The thermocouples Cu + Au 99,4/Co 0,6 and Pt 90/Ir 10 + Au 60/Pd 40 are suitable for the temperature ranges 0 to − 240 °C and 0 to 700 °C, respectively; the gold alloys form the negative leg. Au – Ag – Cu-alloys are used as surface material in sliding contacts.

10.4. Solders [22, pp. 492, 561 – 562], [156], [157, pp. 157 – 163]

A variety of gold-based solder alloys are used in the fields of apparatus technology, electronics, jewelry, and dentistry.

Certain types of apparatus have components made of iron and nickel alloys which have to withstand high vacuums and high temperatures. To join these materials, vacuum hard solders are used, made of either fine gold, or gold – copper, gold – silver – copper, gold – nickel, gold – copper – nickel, and gold – palladium alloys. Soldering is carried out in a vacuum furnace or in a protective gas (hydrogen, cracked gas).

Hard silver solder is normally used to join stainless steels. However, if these joints do not exhibit sufficient corrosion resistance, gold – nickel – zinc alloys similar to white gold, with ca. 80 % gold, 15 % nickel, and 5 % zinc, are occasionally used.

In the fabrication of electronic devices, gold based alloys of the composition gold – tin (25 wt % Sn, *mp* 280 °C), gold – silicon (3.1 wt % Si, *mp* 370 °C), and gold – germanium (12 wt % Ge, *mp* 356 °C) are used.

They allow soldering at relatively low temperatures and give connections of high mechanical strength, good corrosion resistance and thermal conductivity (see also Section 10.3.1).

In jewelry, individual chain links, setting for stones, and hollow-ware parts are soldered with solder alloys which must correspond in cartage, color, and mechanical properties to the materials to be joined, but have melting temperatures that are sufficiently lower to avoid melting of the noble metal pieces [158]. These solder and brazing alloys are principally of the same or similar composition to the metal parts to be joined. For

consecutive solder operation, alloys with different melting temperatures (first, second, third solders) are applied.

Gold-based solder alloys are used in dentistry to join prosthetic dental pieces. Alternative methods are microplasma welding and laser welding. The solder alloys are of similar compositions to the dental alloys. They must correspond to the base materials in their corrosion behavior and thermal expansion. Solders for crowns and bridges melt in the temperature range of around 760 – 840 °C. They are based on the Au – Ag – Cu system with additions of zinc and tin. Melting is usually done by gas torch. Solders for PFM alloys (see also → Dental Materials, Chap. 2.3.) are used before porcelain veneering. The melting temperatures and softening ranges must be sufficiently high so that subsequent baking does not influence the mechanical stability of the solder joint. These solders are based on the Au – Ag system with reduced palladium and platinum content. Color lightening is effected by palladium additions, and the melting temperatures are adjusted by additions of tin, indium, or zinc [159].

Joining of gold and gold alloys at considerably lower temperatures can be performed by using diffusion processes, for instance by using tin foil between components of pure gold and heating the assembly above the melting point of tin but below the melting temperature of gold [160].

10.5. Pen Nibs

Nibs for fountain pens are usually made from Au – Ag – Cu yellow gold alloys which are relatively hard; occasionally white gold alloys are also used. The alloys must be able to withstand the very corrosive ferro-gallic inks; only 14 or 18 carat alloys are suitable. The nib points must be made of hard metal alloys, which usually contain Ru, Os, Ir, W, or Co.

Nibs made of stainless, ink-resistant nickel chromium steel are sometimes coated with a thin layer of gold; however, this does not improve their ink resistance.

10.6. Chemical Technology [161]

Gold – platinum alloys containing 50 – 70 % gold, which can be age-hardened, are used to make spinnerets used in the production of man-made fibers. Their fine-grained structure is of great advantage in making the necessary fine holes (diameter 25 – 120 μm).

Gold alloys are sometimes used for seals and rupture disks that come into contact with corrosive substances. A gold – silver – palladium alloy (Pallacid) containing 30 % gold and 30 % palladium is resistant to strong mineral acids, is considerably cheaper than gold, and also has greater high-temperature strength.

A gold alloy containing 10 % platinum is used to make crucibles for analytical laboratories, e.g., for ash determination of flour and other phosphorus-containing foods. Unlike platinum crucibles, it is resistant to corrosion by phosphorus compounds when red-hot.

10.7. Dental Materials

Gold alloys are of great importance in prosthetic dentistry, for restorations such as gold fillings, crowns, bridges, cast dentures, clasps, anchorage pins, and metal frameworks for dental ceramics (→ Dental Materials). These materials have to meet a number of requirements. They must be resistant to normal conditions in the mouth, of a suitable color, of different strengths, and be easy to work. Today almost all alloys used are of a complex composition, containing high proportions of gold, palladium, and platinum. In the past few years the number of components is decreasing because of allergenic problems. The advantage of these alloys mainly lies in their very fine-grained and homogeneous structure.

10.8. Coatings [162–168]

10.8.1. Electroplating and Electroforming

The technical and decorative properties of gold can be combined with a variety of cheap substrates by applying a thin layer of gold to base metals, ceramics, glass, or plastics.

Electroplating is by far the most frequently used method (→ Electrochemical and Chemical Deposition, Chap. 8.9.). Modern gold electroplating is mainly gold alloy plating for the following reasons:

1) For the adjustment of color. Gold alloys can be deposited in a variety of shades. For example, co-deposition of copper gives a reddish color, nickel a white color, and cadmium a yellow color. Colors of gold alloys are standardized in DIN 5033 and DIN EN 28 654.
2) To improve hardness and wear resistance.
3) In gold alloy deposits part of the gold is replaced by alloying elements which in most cases have a lower density. Thus, substantial savings of gold may be achieved.

Gold coatings are deposited mainly from solutions of potassium dicyanoaurate(I), $K[Au(CN)_2]$. There are three groups of plating solutions:

1) Alkaline cyanide electrolytes, which enable the dissolution of Cu, Ag, Cd and other metal salts and their co-deposition with gold.
2) Neutral electrolytes have been developed for lower carat deposits and higher thicknesses. These electrolytes are also used for pure gold deposits with high thicknesses.
3) Acidic electrolytes (pH 3 – 5) for producing high-carat deposits with properties required by the electronics industry and also for decorative purposes. These electrolytes are based on the finding that solutions of $K[Au(CN)_2]$ are stable at a pH value as low as 3.2. Deposits can be hardened by co-deposition of elements such as Ni, Co, or Fe.

An electrolyte based on the cyanide complex of trivalent gold, $K[Au(CN)_4]$ has been disclosed. The electrolyte is operated at low pH (0.2 – 1.5) and is suitable for difficult-to-plate metals, e.g., stainless steels [164].

Non-cyanide electrolytes contain gold mostly as the sulfito complex $[Au(SO_3)_2]^{3-}$. These plating solutions have a very good throwing power and result in bright crack-free thick deposits with excellent ductility. However, wear resistance is poor. The main drawback of the sulfite electrolytes is the instability of the solution.

Properties of gold coatings which are relevant to their applications are: color, brightness, hardness, wear resistance, porosity, and corrosion resistance. Gold and gold alloy coatings are produced in a wide range of thicknesses (0,1 – 200 µm), depending upon their application.

Electroless or autocatalytic gold-plating solutions usually contain potassium dicyanoaurate(I) together with a reducing agent such as sodium hypophosphite, sodium borohydride, or dimethylamine borane (DMAB). Electroless gold plating is used only where electrolytic processes cannot be used. Typical fields of application are the electronics industry, e.g., in printed circuit boards and in semiconductor electronics [165].

Electroforming (→ Electrochemical and Chemical Deposition) has been defined as "the production or reproduction by electrodeposition of an article on a mandrel or mold, that is subsequently separated from the deposit". Gold up to a thickness of 0.2 mm is deposited on a mandrel, which is then removed. Wax mandrels can be melted out. A self-supporting gold layer is left which can be reinforced by a filler material. A process for depositing 8-, 9-, 14-, or 18-carat gold – silver alloy coatings has been developed [166], [167]. The process of electroforming is also used for manufacturing high-technology equipment [168].

Table 12. Classification of precious metal preparations

Appearance	Consistency	
	liquid/pasty	*solid*
glossy	bright gold bright lemon gold bright palladium bright platinum lusters	
matt	burnish gold burnish palladium burnish platinum	dusting gold dusting white gold dusting silver

10.8.2. Bright Gold

Ceramic materials, especially high-quality porcelain and glass, are often gilded by firing on preparations of bright gold and burnish gold (Table 12, see also → Ceramic Colorants). The essential components of these lacquer-like paints

are gold sulforesinates, mixed with natural oils and resins. The preparations are applied mainly either by hand or by screen printing processes. Firing is carried out at 500 – 1250 °C. Gold coatings for technological applications also may be applied by this method.

Precious metal (PM) preparations for the decoration of ceramic (CerDecOr, dmc^2) materials are classified by:

- Consistency: liquid/pasty or solid
- Appearance: glossy or matt
- Precious metal content: gold, platinum, palladium or silver preparations.

Bright PM preparations are varnishlike organic compounds containing precious metals, combined with flux components (based on organometallic compounds) as adhesion promoters. These preparations also contain resin solutions as film formers. After firing, a high-gloss precious metal film forms on a smooth surface. According to the color shade of the fired product, a distinction is made between:

- *Bright gold*, which develops a typical reddish yellow gold shade after firing and contains a small proportion of silver.
- *Bright lemon gold*, which fires to a lemon-yellow shade, achieved by formation of an gold – silver alloy.
- *Bright platinum* and *bright palladium*, which fire to a white-gold shade, achieved by formation of an Au – Pt or Au – Pd alloy.

Burnish PM preparations are varnishlike organic compounds containing precious metals combined with flux components based on organic metal compounds. The flux compounds promote adhesion, and resin solutions as film formers. A dull precious metal film is formed after firing, which develops a satin surface during subsequent burnishing with a glass-fiber brush, sand, or other compacting materials. Burnish PM preparations are subdivided into:

- *Burnish gold*, which often contains a small portion of silver in addition to gold, enabling the color shade to be varied from reddish yellow to yellow to greenish yellow, depending on the alloy.
- *Burnish platinum* and *burnish palladium*, which fire to a white gold shade, achieved by the formation of an Au – Pt or Au – Pd alloy.
- *Burnish silver*, which is mainly used for the decoration of gift articles and contain only silver as its only precious metal.

To meet the requirements of differing production techniques, two types of *dusting PM preparation* are available, which differ in their particle morphology: **leaf gold flakes** consist of precious metals or their alloys in form of very finely flaked particles. **Painter's gold** is a chemically precipitated, crystalline precious metal powder with mostly spherical particles:

- *Dusting gold* has a typical reddish yellow shade after firing. Preparations with yellow shades can also produced by alloying with silver.
- *Dusting white gold* achieves its color by alloying with platinum and/or palladium.
- *Dusting silver* contains silver which may be modified with a slight fraction of gold.

Dusting PM preparations are primarily used to produce high-grade decals. Decorations produced with dusting gold (leaf gold flakes), dusting white gold, and dusting silver have a permanent attractive metallic appearance without after-treatment. Decorations produced painter's gold (used to hand paint gold decorations) have to be burnished. Dusting silver trends to tarnish after some time.

Lusters are varnishlike preparations, based on metal- and/or precious-metal-containing organic compounds, with resin solutions as film formers. When fired on porcelain, earthenware, enamel, tiles or glass they produce very thin, intensively colored and lustrous layers, which give them their metallic iridescent finish. They are classified according to color shade, precious metal content, and special effects, as indicated by their classification as craquelling or marbling lusters, running lusters, and halo lusters.

Table 13 lists the characteristics of different preparation ranges.

The precious metal content influences mainly the color of the preparations. The differentiation within the range of bright preparations is summarized in Table 14.

Table 13. Characteristics of different preparation ranges

Type of preparation Parameter	Lustres	Bright PMP	Burnish PMP	Matt PMP	Dusting PMP
Surface	glossy, iridescent	glossy	matt after polishing	matt without polishing	semi matt
Condition of the components	liquid	liquid	partly solid	partly solid	solid
Stirring before use	no	no	yes	yes	no
Gold content, %	0 – 6	6 – 15	16 – 40	9 – 15	80 – 100

Table 14. Colors of PM Preparations according to precious metal content

Color	Au, %	Ag, %	Pd, %	Pt, %	Name
Reddish yellow	100				Bright Gold
Yellow	90	10			Bright Gold
Greenish yellow	70	30			Bright Lemon Gold
White	70	10	20		Bright Palladium
White	70	10	10	10	Bright Palladium

10.8.3. Other Gold Coatings

Rolled gold is still used for spectacle frames and gold-plated watches. However, it has lost its former significance in favor of electroplating. Rolled gold is fabricated by soldering gold sheets, usually 14 carat, to blocks made of copper alloy or stainless steel. These are then rolled or drawn to the desired shape, producing strips and wires with a largely non-porous gold coating, usually 5 – 10 µm thick.

Fire Gilding. In this process, the part to be gilded is painted with gold amalgam. The mercury is evaporated by heating, leaving a relatively thick gold layer. The process is very problematical with regard to industrial hygiene.

Vapor Deposition of Gold. To achieve a sufficiently abrasion resistant coating of true gold color, a base layer of TiN is applied which is topped with less than 1 µm of gold [169]. In microelectronics gold layers are deposited for contacts or leads on hybrid ICs by sputtering or evaporation. Sometimes architectural glass is coated with gold instead of silver (reference to low emissivity coatings with Ag in the Ag-chapter). This combines the solar control function with a spectacular decorative effect. Heat protection by thin gold layers also is used in space technology, e.g., in space suits.

10.9. Gold Leaf

Gold leaf is usually made of fine gold or Au – Ag – Cu alloys with a very high gold content. Thin foils are rolled in a package arrangement. Production starts with sheets of about 20 µm thickness. These are placed between sheets of vellum, beaten down, and finally hammered by hand, using separating membranes made of the cecum of cattle ("goldbeater skins") to a thickness of about 0.2 µm [170]. A modern method of making gold leaf is cathode sputtering.

The crystal plane (100) in beaten gold leaf lies in the plane of the leaf. Gold leaf is used to gild wooden statues, book edges, and fabric prints. In certain beverages (Danziger Goldwasser) foods, it is used to achieve visual effects.

In former times, small rolls of gold leaf were used to fill cavities in teeth.

10.10. Catalysts

Gold shows activity in both heterogeneous and homogeneous catalysis.

Gold in platinum group metal and in silver-based catalysts acts as promoter to effect higher yields and higher selectivity. Hydroforming of paraffins and cycloalkanes with gold-containing iridium catalysts gives higher yields of aromatic

compounds at temperatures above 500 °C. Another example is the acetoxylation of ethene to form vinyl acetate over Pd – Au catalysts [171].

Supported active gold catalysts are obtained by coprecipitation or deposition precipitation of gold from precursor compounds on to transition metal oxides such as Mn_2O_3 or Fe_2O_3. The optimum conditions for functionality are gold particle sizes of 2 – 5 nm, which may interact with oxide support that can itself in some way participate in the reaction [172]. They surpass the activity of mercury catalysts for the hydrochlorination of ethyne and are especially suited for the catalytic activated low-temperature oxidation of carbon monoxide [173]. The method of coprecipitation, followed by aging of the gold containing precipitate, which changes thereby from the amorphous to crystalline structure, is important for sustained high activity.

Gold catalysts are also promising in both the selective and nonselective oxidation of hydrocarbons, in the reduction of nitrogen oxides by carbon monoxide, propene, or hydrogen, in the hydrogenation of carbon oxides [172], and in the epoxidation of propane with O_2/H_2 mixtures [174].

Gold on carbon catalysts have been used for the selective liquid-phase oxidation of diols with dioxygen in alkaline solution under mild conditions (343 – 363 K). As with gold catalysts in the gas phase, the gold particle size is important. Particle size was 7 nm, the catalyst was prepared by deposition precipitation from $H[AuCl_4]$ and sodium carbonate, followed by reduction with formaldehyde [175].

Homogeneous catalytic action is shown by cationic gold(I) phosphine complexes in the addition of alcohols to alkynes. These gold catalysts are also significantly better than the previously used mercury catalysts and work under mild conditions (20 – 50 °C) in the presence of acidic co-catalysts [176], [177].

Platinum vapor, which forms from platinum – rhodium catalysts during the oxidation of ammonia to nitric acid can be retained by a gold or gold – palladium gauze. This process has long been in industrial use.

11. Economic Aspects [2], [4], [18–20], [39], [40], [47], [178–180]

Production. Gold represents a significant portion of the total world economy. In the Republic of South Africa, it occupies in terms of value the highest position among all industrial goods. About 500 000 people are employed worldwide in gold production 300 000 – 400 000 of them in the Republic of South Africa. The value of the gold from primary production in 1997 was about € 20×10^9. Thus it occupies third place in the metal trade, after pig iron (€ 100×10^9) and aluminum (€ 23×10^9), and before copper (€ 11×10^9) [178]. Global gold mine production grew from 390 t in 1900 to 2576 t in 1999 [178].

At present, almost half of the gold obtained from ores is produced in the Republic of South Africa, The United States, Canada, and Australia. Table 15 shows the primary production of gold in the various producer countries [179].

Table 15. Global mine production of Gold 1998 and 1999 in t [179]

Country	1998	1999
South Africa	464	450
United States	366	342
Australia	310	303
Canada	164	158
China	160	156
Indonesia	139	155
Russia	127	138
Peru	91	127
Uzbekistan	80	86
Ghana	73	78
PNG	63	65
Brazil	55	54
Chile	47	48
Argentina	20	35
Philippines	35	32
Zimbabwe	27	30
Mali	23	25
Mexico	26	23
Colombia	22	21
Kyrgyzstan	21	20
Rest of World	226	231
Total	2541	2576

Supply and Demand. The supply of gold on the market in 1997 was about 2700 t/a (Fig. 32). Most of this (73 %) came from total world mine production, 20 % came from recycling processes, and 7 % was sold by the former Soviet Union. Buying and selling on the part of government monetary authorities can have a strong effect on the market; in recent years official sector sales have increased significantly.

Figure 33 shows the demand for gold according to industrial applications.

Gold Trade. London is the most important market for gold in terms of the quantity traded. The London gold market has a fixing system, whereby the price of gold is determined twice daily, according to supply and demand, by representatives from five firms of brokers. This is then published as the "fixing price". The United States futures markets have a strong influence on the calculation of this price. The fixing price serves as an orientation point for gold traders all over the world.

Zurich is also an important center of the gold trade. A considerable part of the gold from South African primary production, which up to 1968 all went to London, is now sold to Zurich, as well as most of the gold from the Soviet Union.

Another important center is New York. Other metal exchanges, such as Hongkong, Frankfurt, Paris, Singapore, and Tokyo, are of more regional importance.

Gold is traded internationally in the form of gold bars of various weights, and with a gold content of 99.50 – 99.99 %. In London, gold bullion must contain gold weighing between 350 and 430 oz; the commonest figure is about 400 oz (ca. 12 kg).

Important factors which influence the price of gold are assessment of political circumstances, inflation rates, and the rate of interest of the US dollar as a key world currency. The huge gold holdings of central banks and several central bank disposals had been weighing on the price of gold in 1997 and 1998 together with increasing amounts of gold forward sales of producers. On August 28, 1998, the price of gold was fixed at $ 273.40 per ounce – at that time a fresh 19 year low.

12. Toxicology and Occupational Health

Gold and its soluble compounds generally only seldom cause acute or chronic problems in the workplace and in the environment. Tetrachloroauric acid $H[AuCl_4]$ [*16903-35-8*] as is a strong acid with corrosive effects on the skin. Gold(III) salts are more poisonous than gold(I) compounds. After intake of gold(III) chloride lethal poisonings with toxic effects on liver and kidneys are observed. Potassium dicyanoaurate $K[Au(CN)_2]$ [*14265-59-3*] liberates hydrocyanic acid, which can cause poisoning. Poisonings by high doses of other gold compounds are also known [181], [182].

The daily intake of gold in food is estimated at less than 7 µg. Usual concentrations in blood are 15 µg/L [183] or over less than 0.5 µg/L, with an average of 0.1 µg/L [184].

Gold Therapy. Gold compounds are used in the treatment of chronic rheumatoid arthritis and of pemphigus vulgaris in dermatology. A 30 % incidence of side effects is known [185]. Therapeutic effects and toxicity correspond with water solubility [186]. Medical treatment uses weakly soluble gold(I) thiolates such as Myocrysin (disodium gold(I) malate [*42722-04-3*]) or Solganol or Aureotan (gold(I) thioglucose [*12192-57-3*]). The drug is administered by intramuscular injection in relatively high doses. Toxic side effects include cardiovascular disorders, nerve dysfunction and adverse effects on liver, stomach, and bone marrow. Allergic effects occur on the skin, mucous membranes, and, rarely, in the lungs. The development of drug-induced lichen planus is also possible [185].

A possible consequence of chronic gold application is chrysiasis, a blue gray discoloration of the skin, similar to argyria [185].

Gold Allergy. Skin allergies to gold jewelry or dental gold have rarely been observed. In many cases they could be attributed to less precious alloying elements such as nickel, cobalt, or copper.

1. Introduction

Gout is an exclusively human disease. Its cardinal manifestations are high serum urate levels (hyperuricemia) and recurrent episodes of acute arthritis. In its fully developed form, gout also results in deposition of uric acid in the kidneys (nephrolithiasis), interstitial renal disease, and deposition of monosodium urate monohydrate aggregates (tophi) in and around joints (chronic tophaceous gout).

History. The term gout was first introduced in the 13th century, although its clinical manifestations had been described by Hippocrates in the 5th century B.C. [1]. In the 17th century, Sydenham distinguished gout from other arthritidies [2]. The importance of uric acid in the pathogenesis of this disease was elucidated in the 19th century [3].

An understanding of the pathogenesis of gout has lead to the development of specific therapies. Although colchicine has been used for centuries to treat acute gouty arthritis, newer anti-inflammatory agents are now used to manage acute attacks [4]. In addition, effective antihyperuricemic therapy has been developed. These agents decrease serum urate, reduce the total body pool of uric acid, prevent urate deposition, and promote dissolution of preformed tophi and stones.

Biochemistry. Uric acid is the ultimate degradative product of purine metabolism in humans. It is derived primarily from the breakdown of nucleic acids, nucleotides, and ingested, preformed purines. The proximate steps in uric acid formation are dephosphorylation of ribonucleotides and deoxyribonucleotides to their nucleoside forms, adenosine and guanosine. Adenosine and guanosine are both converted to inosine. Purine nucleoside phosphorylase converts inosine to hypoxanthine in a freely reversible reaction. Hypoxanthine, thus generated, is a substrate for the iron-containing flavoenzyme, xanthine oxidase. Xanthine oxidase converts hypoxanthine to xanthine, and then xanthine to uric acid.

Thus, the production of uric acid is dependent upon the rate of purine nucleotide degradation and the subsequent oxidation of hypoxanthine. The serum concentration of uric acid reflects the difference between this production rate and the net excretion rate of uric acid. Under normal conditions, two-thirds of the daily production of uric

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a12_535

acid is excreted in the urine. The remaining fraction is excreted through the intestine where uric acid is cleaved by the action of bacterial uricases.

Epidemiology. Hyperuricemia denotes an elevation of serum urate concentration and may be defined on either a physicochemical or an epidemiologic basis. Physicochemically, serum is saturated with urate at concentrations exceeding 7 mg/dL as measured by the uricase method at 37 °C [4]. In sex- and age-matched populations, relative hyperuricemia is present when the serum urate concentration exceeds two standard deviations above the mean. In postpubertal men, this value is 7 mg/dL; in postpubertal females, 6 mg/dL [4]. Epidemiologically, an increased risk for development of gout and kidney stones exists when the serum urate concentration exceeds 7 mg/dL [4]. In the majority of subjects, however, hyperuricemia is asymptomatic. Only a small fraction of hyperuricemic individuals develop gout [5].

The serum urate concentration varies with age and sex [6–8]. Values range from 3 to 4 mg/dL in children. With the onset of puberty, serum urate concentration normally rises in males to 4 – 6 mg/dL and remains at that level throughout life. In females, the serum urate concentration typically remains unchanged until the menopause at which time it approaches values comparable to those in adult males. Factors such as blood pressure, serum creatinine, height, weight, age, and alcohol intake correlate with serum urate concentration [9–12].

Serum urate levels above 7 mg/dL are found in 6.5 – 9.3 % of adult males [4]. Among women, 6.3 % have serum urate values >6 mg/dL [4]. The development of gout depends on the degree and duration of serum urate elevation. Therefore, the prevalence of gout increases with age and with the degree of hyperuricemia [11, 12]. The annual incidence of gout is 0.1 % for urate levels less than 7 mg/dL and 4.9 % for levels greater than 9 mg/dL [13].

Symptoms and Treatment. Gout is manifested clinically by recurrent episodes of acute arthritis. Intraleukocytic crystals of monosodium urate monohydrate are found in synovial fluid from inflamed joints [14].

An acute attack of gout is generally self-limited and confined to a single joint (monoarticular). Recurrent episodes follow, which tend to become polyarticular. The frequency of attacks increases with time and leads to disabling chronic arthritis. Prompt diagnosis and implementation of therapy at the onset of an acute attack shorten the episode and relieve the disabling pain. Prophylactic therapy aimed at preventing recurrent arthritis significantly reduces the risk of chronic arthritis and joint deformity [15]. Antihyperuricemic agents lower the serum urate concentration and thus promote solubilization of tophi. Reduction of serum urate levels also decreases the risks of recurrent arthritis, uric acid nephrolithiasis, and urate nephropathy, as well as the development of chronic gouty arthritis.

2. Gout and Hyperuricemia

2.1. Pathophysiology

Hyperuricemia may result from insufficient excretion of uric acid by the kidneys, endogenous overproduction of uric acid, or a combination of both. *Primary hyperuricemia* develops independently of other diseases and is unrelated to drug use. *Secondary hyperuricemia* is either a manifestation of an underlying disease or the result of an ingested drug or toxin.

Impaired Renal Uric Acid Excretion. The most common cause of hyperuricemia is diminished uric acid excretion by the kidneys. Although this accounts for approximately 90 % of cases of primary hyperuricemia [16], the reason has not been established; impaired urate clearance has been documented in these patients [17–21].

Underlying renal disease, drugs, or toxins may also impair the ability of the kidney to excrete uric acid and result in secondary hyperuricemia. Intravascular volume contraction resulting from diuretic therapy, adrenal insufficiency, or liver disease leads to secondary hyperuricemia due to diminished glomerular filtration and increased tubular reabsorption of uric acid [22, 23]. Drugs such as ethanol, ethambutol, and nicotinic acid may diminish renal clearance of uric acid [24]. Organic acids inhibit uric acid secretion by the kidneys. Therefore, diseases resulting in metabolic acidosis may also lead to hyperuricemia [24].

Overproduction of Uric Acid. Endogenous overproduction of uric acid accounts for approximately 10 % of cases of primary hyperuricemia [16]. Overproduction is characterized by a high level of uric acid in the urine (hyperuricaciduria), which is the result of accelerated purine synthesis. The etiology of urate overproduction in primary hyperuricemia is unknown in the majority of cases, but it may be due to specific inborn errors of metabolism. Patients with 5-phosphoribosyl-1-pyrophosphate synthetase overactivity or partial hypoxanthine phosphoribosyltransferase (HPRT) deficiency demonstrate primary hyperuricemia [4].

Endogenous urate overproduction caused by the following factors may also lead to secondary hyperuricemia:

1) Inborn enzyme defects resulting in overproduction of uric acid, e.g., the Lesch–Nyhan syndrome, glucose 6-phosphatase deficiency, and the glycogen storage diseases types I, III, V, and VII [24]
2) Myeloproliferative disorders leading to accelerated nucleic acid turnover
3) Increased adenosine triphosphate (ATP) degradation caused by alcohol consumption or tissue hypoxia [24]

Urate Precipitation. The acute attack of gout is triggered by precipitation of monosodium urate monohydrate crystals in or near a joint [6,25,26]. The cause of this precipitation is unclear, and hyperuricemia is not essential. The inflammatory response to intra-articular urate crystals includes activation of the kallikrein–kinin and complement systems, formation of leukotrienes, platelet activation, prostaglandin synthesis [16], and leukocyte migration. The leukocytes phagocytose the urate crystals and release chemotactic factors. Intracellular urate crystals cause lysosomal disruption and cell injury. Release of lysosomal enzymes into the joint space leads to further inflammatory changes including increased capillary permeability and tissue damage. For a detailed description of inflammation, see → Anti-inflammatory – Anti-rheumatic Drugs, Chap. 1.

2.2. Clinical Manifestations

Articular Disease. The clinical spectrum of gout encompasses four stages:

1) asymptomatic hyperuricemia,
2) acute gouty arthritis,
3) intercritical gout, and
4) chronic tophaceous gout [16].

Asymptomatic hyperuricemia is characterized solely by elevation of the serum urate concentration. *Acute gouty arthritis* is usually the first clinical manifestation of gout and often occurs after years of asymptomatic hyperuricemia. The first attack is usually monoarticular and develops rapidly. The most commonly affected joint is the metatarsal–phalangeal joint of the big toe [27], but other joints may be affected [16]. Pain, swelling, and redness develop and intensify within a few hours. Untreated acute gout is generally self-limited; symptoms persist from several hours to weeks in severe attacks.

In *intercritical gout* the first attack of gouty arthritis is followed by a variable, asymptomatic period. The majority of patients experience the second attack within six months to two years, but the asymptomatic (intercritical) period may be ten years or longer [16]. During the phase of intercritical gout, the asymptomatic periods between acute attacks shorten. The arthritis becomes polyarticular, and if untreated, chronic persistent arthritis may develop [16,24].

Chronic tophaceous gout is characterized by chronic polyarticular arthritis and development of tophi in and around joints and in soft tissues [16]. Joint erosion and destruction occur, which may be accompanied by marked deformity and crippling of hands and feet.

Renal Disease. The clinical manifestations of hyperuricemia are not limited to articular disease; three types of renal disease are also found: (1) uric acid nephropathy, (2) urate nephropathy, and (3) nephrolithiases.

Uric acid nephropathy results from precipitation of uric acid within the collecting ducts of the kidneys [16]. It is typically associated with marked hyperuricemia and hyperuricaciduria. Uric acid nephropathy is seen most frequently in lymphoproliferative disorders following chemotherapy [28–30], when the large

nucleic acid pool liberated by tumor cell lysis leads to marked hyperuricemia. Acute renal failure may occur.

Urate nephropathy is caused by deposition of monosodium urate monohydrate in the renal interstitium [16]. Unlike uric acid nephropathy, it does not cause acute renal failure but may contribute to the chronic renal insufficiency of gouty patients.

Nephrolithiasis. Gouty patients have an increased prevalence of kidney stones [16, 31, 32]. Renal calculi occur in 10 – 25 % of patients with primary gout and in as many as 42 % of patients with secondary gout. The incidence of stone formation increases with increasing serum urate concentration and urinary uric acid excretion [31, 32].

Other Disorders. Several other disorders are associated with hyperuricemia and gout; these include hypertension, obesity, hyperlipidemia, and diabetes mellitus, as well as cerebrovascular and cardiovascular disease [16]. No direct cause and effect relationship has been established between these disorders and hyperuricemia.

3. Treatment

Medical management of gout is undertaken to:

1) promote rapid resolution of acute arthritis;
2) reduce the likelihood of recurrent gouty attacks;
3) lower the serum urate concentration, thereby inhibiting urate deposition and promoting dissolution of tophi; and
4) prevent uric acid nephrolithiasis.

3.1. Drugs Used to Treat Acute Gout

3.1.1. Colchicine

Colchicine [*64-86-8*], (*S*)-*N*-(5,6,7,9-tetrahydro-1,2-3,10-tetramethoxy-9-oxobenzo[α]heptalen-7-yl)acetamide, is an alkaloid of the plant *Colchicum autumnale*. The plant has been used in the treatment of articular disorders since the sixth century A.D. [33] and colchicine has been used to treat gout for over two centuries. This anti-inflammatory drug is uniquely effective against gouty arthritis (see also → Alkaloids; → Anti-inflammatory – Antirheumatic Drugs).

Colchicine

Colchicine impairs leukocyte migration, thereby inhibiting the inflammation responsible for acute gouty attacks [34]. Colchicine has also been shown to inhibit lysosomal degranulation, phagocytosis, and neutrophil adherence [34–39]. The drug binds to microtubular structures and arrests cell division [33].

Colchicine is administered orally or intravenously [33]. Peak plasma levels occur 0.5 to 2 h after an oral dose. The drug is eliminated principally through feces; ca. 10 – 20 % is eliminated in the urine.

Oral colchicine is used to treat acute gouty arthritis [16]. The drug is most effective when administered within the first few hours of an attack at a dose of 0.5 or 0.6 mg/h until symptoms subside or gastrointestinal side effects develop (maximum total dosage 6.0 mg). Symptoms usually improve within 12 h and often completely resolve within three days. As many as 50 – 80 % of patients develop gastrointestinal side effects before relief from arthritis occurs. Daily oral colchicine (0.5 – 1.0 mg) is useful in preventing recurrent episodes of acute gout [16].

Intravenous colchicine effectively terminates acute attacks of gout without causing gastrointestinal side effects [16]. It is administered intravenously as a single 2-mg dose in 20 mL of saline, followed by 1-mg dosages every 6 h up to a maximum of 4 – 5 mg. Complications include local extravasation with inflammation and skin necrosis, as well as bone marrow suppression.

3.1.2. Nonsteroidal Anti-inflammatory Drugs

Several nonsteroidal anti-inflammatory drugs have been employed in the treatment of acute gout. These drugs are thought to exert their anti-inflammatory effects by inhibiting prostaglandin synthesis, inhibiting leukotriene syn-

thesis, and preventing free-radical formation [40]. Prostaglandins are potent mediators of inflammation. The nonsteroidal anti-inflammatory agents reversibly inhibit cyclooxygenase, an enzyme that converts arachidonic acid to prostaglandin precursors [40]. Prostaglandin synthesis is thereby suppressed. Leukotrienes, also derived from arachidonic acid, have been implicated in leukocyte aggregation, degranulation, and free-radical formation [40]. Some nonsteroidal anti-inflammatory agents inhibit leukotriene synthesis and presumably modify the inflammatory response by interfering with these mechanisms.

Oxygen free radicals are formed during the synthesis of prostaglandins and can cause tissue injury. Inhibition of prostaglandin synthesis by nonsteroidal agents suppresses free-radical formation [40].

(For physical properties, syntheses, and trade names of the drugs treated in this section see → Anti-inflammatory – Antirheumatic Drugs).

Indomethacin [*53-86-1*], 1-(4-chlorobenzoyl)-5-methoxy-2-methyl-1*H*-indole-3-acetic acid (Indocin) is rapidly absorbed from the gastrointestinal tract. Peak plasma levels are obtained within 3 h of ingestion [33], and the drug is highly bound to plasma proteins. It is eliminated in both urine and feces, 10 – 20 % being excreted unchanged in the urine. Approximately 50 % of a given dose undergoes O-demethylation, and 10 % is conjugated with glucuronic acid.

Indomethacin

For treatment of acute gout, indomethacin is administered at a 50 – 75-mg dosage, followed by 50 mg every 6 h for a maximum dose of 200 mg in the first 24 h [16]. The dosage is subsequently reduced [16].

Indomethacin may also be used for gout prophylaxis [16]. A daily dose of 25 – 50 mg is usually sufficient to prevent recurrence of acute attacks.

Phenylbutazone [*50-33-9*], 4-butyl-1,2-diphenyl-3,5-pyrazolidinedione (Butazolidin) has

Phenylbutazone

been used for over 30 years to treat acute gout [41, 42]. After oral administration, peak plasma concentration is reached within 2 h [33]. The drug is completely absorbed from the gastrointestinal tract and 98 % is bound to plasma proteins. Plasma half-life ranges from 50 to 100 h. The drug undergoes glucuronidation and hydroxylation, and is excreted primarily in the urine. Oxyphenylbutazone, an active metabolite of phenylbutazone, has a long plasma half-life and contributes to the side effects of phenylbutazone. Oxyphenylbutazone is also excreted in the urine after glucuronidation [33].

For treatment of acute gout, phenylbutazone is administered at an initial dosage of 200 mg – 600 mg [16], followed by 100 – 200 mg every 6 – 8 h for 24 h (maximum dose = 600 mg/d). The dosage is then reduced and discontinued after two days.

Side effects of phenylbutazone include hypersensitivity reactions, gastric discomfort, peptic ulcer disease, and fluid retention [33]. Deaths from aplastic anemia have been reported [43].

Naproxen [*22204-53-1*], (*S*)-6-methoxy-α-methyl-2-naphthaleneacetic acid (Naprosyn) was effective in acute gout management in several clinical trials [44]. It is fully absorbed after oral administration [33]. Plasma half-life is 12 – 15 h. The drug is extensively bound to plasma protein and eliminated in the urine. Approximately 30 % undergoes 6-demethylation prior to elimination. To treat acute gout, naproxen is administered at an initial dose of 500 – 750 mg, followed by 250 mg every 8 h until the acute attack subsides [16].

Naproxen

Ibuprofen [*15687-27-1*], α-methyl-4-(2-methylpropyl)benzeneacetic acid (Motrin) is absorbed efficiently from the gastrointestinal tract [33]. Maximum plasma levels are achieved within 1 – 2 h, and its half-life is approximately 2 h. Like naproxen, ibuprofen is almost completely bound to plasma proteins and is eliminated principally via the urine. It is metabolized prior to elimination in the urine. Ibuprofen has demonstrated efficacy in the treatment of acute gout [45]. A dosage of 800 mg every 8 h is given until symptoms are resolved [16]. The dose may then be reduced.

Ibuprofen

Fenoprofen [*31879-05-7*], (±)-α-methyl-3-phenoxybenzeneacetic acid (Nalfon) is rapidly absorbed, and peak plasma concentrations are achieved within 2 h of oral administration [33], [46, pp. 890 – 891]. The plasma half-life is approximately 3 h. Fenoprofen is highly bound to plasma protein, and its major urinary metabolites are fenoprofen glucuronide and 4′-hydroxyfenoprofen glucuronide. Over 90 % of the drug is metabolized prior to elimination in the urine. Successful termination of an acute gout attack may be achieved with a dosage of 800 mg every 6 h [16]. The dose is then tapered when symptomatic improvement occurs.

Fenoprofen

Sulindac [*38194-50-2*], (*Z*)-5-fluoro-2-methyl-1-{[4-(methylsulfinyl)phenyl]methylene}-1*H*-indene-3-acetic acid, (Clinoril) is approximately 90 % absorbed after oral administration [33]. The active sulfide metabolite is formed by oxidation to the sulfone and subsequent reduction. Sulindac has a plasma half-life of 7 h; the sulfide metabolite has a half-life of 18 h. Sulindac and its metabolites are extensively protein bound. Excretion of the drug occurs in the urine and feces. Approximately 50 % of the administered dose is eliminated in the urine, the major product being the conjugated sulfone. Sulindac administered at a dosage of 200 mg twice a day is effective in terminating an acute attack of gout [47].

Sulindac

Piroxicam [*36322-90-4*], 4-hydroxy-2-methyl-*N*-2-pyridyl-2*H*-1,2-benzothiazine-3-carboxamide-1,1-dioxide (Feldene) is well absorbed after oral administration, and peak plasma concentrations are achieved within 3 – 5 h [46, pp. 1558 – 1559]. Mean plasma half-life is 50 h. The drug is excreted in both urine and feces, the majority being excreted as metabolites formed by hydroxylation and conjugation, cyclodehydration, and hydrolysis of the amide linkage, decarboxylation, ring contraction, or N-demethylation. Piroxicam administered at a daily dose of 20 mg, effectively suppresses or completely relieves symptoms of acute gouty arthritis within five days [48–50].

Piroxicam

3.1.3. Corticosteroids

Corticosteroids have both anti-inflammatory and immunomodulatory properties [16]. They inhibit arachidonic acid release from phospholipids, thereby inhibiting prostaglandin synthesis. They are also purported to stabilize lysosomal membranes, inhibit cellular metabolism,

decrease serum immunoglobulins, and diminish synovial permeability. Intra-articular corticosteroids are particularly effective in suppressing acute gouty arthritis [51]. Commonly used intra-articular steroids include methylprednosolone acetate (Depo-medrol), triamcinolone acetonide (Kenalog), and triamcinolone hexacetonide (Aristopan). Relief of symptoms usually occurs within 12 h. This form of treatment may be employed when one or two joints are involved and the patient is unable to tolerate other forms of therapy. Many different corticosteroid preparations are available. For structure, properties, and preparation, see → Hormones.

3.2. Antihyperuricemic Drugs

The antihyperuricemic drugs consist of (1) uriscosuric drugs which increase urinary uric acid excretion and (2) xanthine oxidase inhibitors which inhibit uric acid synthesis. The aim of antihyperuricemic therapy is to lower the concentration of serum urate below 6.4 mg/dL [16].

The selection of an antihyperuricemic agent should be based on the cause of the hyperuricemia and the condition of the patient. Patients without kidney problems who excrete less than 700 mg of uric acid per day may be treated with either uricosuric agents or xanthine oxidase inhibitors [24]. Patients who excrete more than 700 mg of uric acid a day should be treated with xanthine oxidase inhibitors. Antihyperuricemic agents should not be given until an acute gouty attack has subsided because they may exacerbate such attacks [16]. In addition, they may also precipitate the onset of acute gouty arthritis. Patients should, therefore, be treated prophylactically with colchicine or indomethacin prior to the introduction of antihyperuricemic medication.

3.2.1. Uricosuric Drugs

Uricosuric drugs increase the rate of excretion of uric acid by interfering with its reabsorption by the renal tubules [52]. They reduce serum urate levels in the majority of patients but are generally ineffective in patients with marked renal insufficiency [16]. Concomitant administration of salicylate blocks their uricosuric effect [52].

The use of uricosuric drugs should be accompanied by liberal intake of fluids to prevent crystallization of uric acid within the urinary tract. Alkalinization of urine by the administration of sodium hydrogen carbonate or potassium citrate may prevent formation of kidney stones [24].

Probenecid [*57-66-9*], 4-[(dipropylamino)-sulfonyl]benzoic acid (Benemid) inhibits epithelial transport of organic acids [52]. It is completely absorbed after oral administration, with peak plasma levels achieved in 2–4 h. It is extensively bound by plasma proteins and has a plasma half-life of approximately 9 h. Probenecid is eliminated in the urine. Metabolism may occur by hydroxylation or conjugation to glucuronide [52].

Probenecid

Probenecid is administered at a dose of 250 mg twice a day for one week; the dosage is then increased up to a maximum of 2 g per day [46, pp. 1246–1247].

Adverse side effects to probenecid include gastrointestinal irritation, hypersensitivity reactions, and central nervous system abnormalities [52].

Sulfinpyrazone [*57-96-5*], 1,2-diphenyl-4-[2-(phenylsulfinyl)ethyl]-3,5-pyrazolidinedione (Anturane) is a strong organic acid [52]. Although sulfinpyrazone inhibits reabsorption of uric acid, like probenecid it interferes with tubular secretion of other organic acids. It is absorbed efficiently from the gastrointestinal tract and is extensively bound to plasma proteins. This drug is excreted in the urine, with 10 % being the N1-*p*-hydroxyphenyl metabolite.

Sulfinpyrazone

Sulfinpyrazone is administered initially at a dose of 50 – 100 mg twice a day, which can be increased gradually to a daily dosage of up to 800 mg [46, pp. 833 – 834].

Side effects include gastrointestinal irritation, hypersensitivity reactions, and blood dyscrasias [52]. In addition, this drug may potentiate the action of certain sulfonamides such as sulfadiazine and sulfisoxazole [46, pp. 833 – 834].

Benzbromarone [*3562-84-3*], (3,5-dibromo-4-hydroxyphenyl)(2-ethyl-3-benzofuranyl)methanone, is a potent uricosuric agent with demonstrated efficacy in reducing serum urate levels [53–55]. Onset of uricosuric activity is rapid, with peak uric acid excretion occurring at approximately 5 h Benzbromarone does not affect tubular secretion of other organic acids. The usual maintenance dose is between 50 and 100 mg a day [53–56]. Side effects include diarrhea, allergy, and urolithiasis [53, 54, 56].

Benzbromarone

Benziodarone [*68-90-6*] (2-ethyl-3-benzofuranyl)(4-hydroxy-3,5-diiodophenyl)methanone, and **zoxazolamine** [*61-80-3*], 5-chlorobenzoxazolamine, have uricosuric activity [57, 58], but neither agent is used clinically in the United States to manage hyperuricemia.

Benziodarone

Zoxazolamine

3.2.2. Xanthine Oxidase Inhibitors

Xanthine oxidase catalyzes the oxidation of hypoxanthine to xanthine and of xanthine to uric acid [24]. Allopurinol and its oxidation product oxipurinol are structural analogues of hypoxanthine and xanthine, respectively. Both inhibit xanthine oxidase, thereby diminishing uric acid synthesis and lowering serum urate concentration.

Allopurinol [*315-30-0*], 1,5-dihydro-*H*-pyrazolo[3,4-*d*]pyrimidin-4-one (Zyloprim) is absorbed rapidly from the gastrointestinal tract [33]. Peak plasma levels occur within 30 – 60 min of an oral dose, and plasma half-life is 2 –3 h. Allopurinol is metabolized to oxipurinol [*2465-59-0*]. Oxipurinol, 1*H*-pyrazolo[3,4-*d*]-pyrimidine-4,6(5*H*,7*H*)-dione is cleared slowly from plasma and has a half-life of 15 – 20 h [46, pp. 818 – 820]. Both compounds are biologically active and neither is protein-bound [33]. Only 10 % of a single dose of allopurinol is excreted unchanged in the urine.

Allopurinol

The usual dosage of allopurinol is 300 mg administered once a day. The serum urate concentration falls within the first two days of therapy, and the minimum serum urate construction is achieved within two weeks [24]. The dose of allopurinol may gradually be increased to a maximum of 800 mg daily [46, pp. 818 – 820]. Dosages above 300 mg should be given twice daily. In patients with renal insufficiency, the half-life of oxipurinol is increased and the dose of allopurinol should be reduced.

Side effects of allopurinol therapy include acute gouty arthritis, hematologic abnormalities, gastrointestinal intolerance [33], and life-threatening hypersensitivity reactions.

Allopurinol may interfere with the hepatic metabolism of oral anticoagulant drugs and must be used with caution in this context [33]. Azathioprine and 6-mercaptopurine are potentiated when administered concomitantly with allopurinol. The combined administration of allopurinol and uricosuric drugs may improve serum uric acid control [33].

3.3. Dietary Management

The aims of dietary management in gout are to reduce body weight, alcohol intake, and ingestion of foods known to trigger acute attacks [16]. Patients with gout are often overweight [16]; weight reduction may lower the serum urate concentration [59].

Alcohol intake may lead to hyperuricemia and gout [60], therefore patients with gout should reduce or discontinue alcohol consumption.

Ingestion of certain, often purine-rich, foods may be associated with the development of acute gouty arthritis in some patients [16]. Specific foods known to precipitate acute attacks of gout should be avoided. Examples of purine-rich foods are herrings, sardines, liver, sweetbreads, kidneys, and brewer's yeast. Severe dietary restriction of purine is usually unnecessary, but patients should avoid excessive purine intake. High-protein diets should also be avoided because endogenous purine production is increased by excessive protein consumption [16].

Obesity, hyperlipidemia, and hypertension are associated with gout and hyperuricemia [16]. Management of these conditions with diet, exercise and appropriate medications is important in prolonging life and preventing the complications of these associated conditions.

Guanidine salts are made from cyanamide or dicyandiamide by addition of ammonium salts. The highly soluble guanidine hydrochloride is mainly used in pharmaceutical and biotech applications, while guanidine nitrate is used in propellants and explosives.Nitroguanidine, prepared by nitration of guanidine nitrate, is used for explosives and as a building block for neonicotinoid insecticides. Aminoguanidines, prepared from hydrazines and cyanamide or guanidines, are mainly used for agrochemicals and — due to their high nitrogen content — as a component for propellants and gas generators.Organoguanidines can be prepared from cyanamides or cyanogen chloride. They are used as building blocks for agrochemicals and pharmaceuticals, and as curing agents for plastics and rubbers. Biguanides can be obtained from dicyanamide or cyanoguanidines, they are mainly used as pharmaceuticals and biocides.

1. Guanidine and Guanidine Salts

Guanidine [*113-00-8*], CH_5N_3, M_r 59.08, was first isolated in 1861 by Strecker as a degradation product of guanine [*73-40-5*].

Although free guanidine or guanidine salts naturally occur only in trace amounts [1], many guanidine derivatives are important components of living organisms [2 – 4]. Guanidine and its derivatives have a wide field of application, e.g., as building blocks in the synthesis of pharmaceutical and agricultural chemicals, in the manufacture of textiles and plastics, and also in biochemistry [5 – 8].

1.1. Properties

Free guanidine can be isolated from guanidine salts by reaction with a strong base such as an

© 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a12_545.pub2

alkali metal hydroxide or methoxide. After removal of the precipitated salt the free guanidine base is obtained as colorless, waxy, very hygroscopic crystals (*mp* <50 °C).

Guanidine is a strong monobasic Brønsted base, which absorbs water and carbon dioxide from the air and forms strongly alkaline solutions with water and alcohols; the pH of a 20 wt % aqueous solution is ca. 13.5 (25 °C). In aqueous solution at elevated temperature guanidine is hydrolyzed to urea; airtight alcohol solutions are stable. Guanidine is infinitely soluble in water, ethanol, methanol, and dimethylformamide.

Protonation of guanidine gives the mesomeric, highly stabilized guanidinium cation:

Guanidine forms stable, easily crystallizable salts with acids, even with a weak acid such as stearic, carbonic, or silicic acid. Some physical properties of various guanidine salts are listed in Table 1.

Salts of guanidine should, according to IUPAC nomenclature, be named as guanidinium compounds. In this article, however, common (although technically incorrect) names will be used, e.g., guanidine nitrate rather than guanidinium nitrate.

The very stable guanidinium cation is unreactive, so reactions of guanidine with organic compounds are usually carried out under strongly alkaline conditions. Like other amines, guanidine undergoes alkylation, acylation, methylolation, and condensation. Many guanidine derivatives are synthesized from guanylating agents such as cyanamide [*420-04-2*] (→ Cyanamides) or *O*-methylisourea [*2440-60-0*] (see Sect. 2.4) because of the relatively low reactivity of guanidine itself.

The most important reaction of guanidine is the formation of heterocyclic compounds such as pyrimidines, imidazoles and oxazoles. Guanidine condenses with bifunctional compounds such as diketones, acetoacetic acid esters, and malononitrile [*109-77-3*], eliminating ammonia or water to form 2-aminoheterocycles, for example:

Nitration of guanidine leads to nitroguanidine (see Chap. 2.1), while chlorination with elemental chloride or sodium hypochlorite leads to *N,N″*-dichloro-diazenedicarboxamidine (azochloramide, [*502-98-7*]).

1.2. Production

No practical method exists for the direct synthesis of free guanidine. All major manufacturing processes therefore involve the production of guanidine salts by reaction of the appropriate ammonium salt with compounds containing the NCN group. At present, only *dicyandiamide* [*461-58-5*] (→ Cyanamides, Chap. 3), *cyanamide* (→ Cyanamides, Chap. 2), and *urea* [*57-13-6*] (→ Urea) are used for large-scale production of guanidine salts.

1.2.1. Guanidine Salts from Dicyandiamide

Dicyandiamide is by far the most important raw material for the production of guanidine salts. Earlier processes conducted in acidic aqueous solution with guanylurea as an intermediate [5] have been abandoned. At present, guanidine salts are manufactured by fusing dicyandiamide with ammonium salts, with biguanide [*56-03-1*] as an intermediate:

When carried out in batches in open stainless steel vessels at atmospheric pressure, reaction begins above 130 – 140 °C and becomes exothermic at 170 °C. The temperature is allowed to rise to 210 – 230 °C and is maintained

within this range until the reaction has reached completion. The molten mass is then dissolved in water or mother liquor; insoluble triazine byproducts are filtered off. The guanidine salt is crystallized by cooling or concentration of the filtrate, centrifuged, washed, and dried.

Large-scale production of guanidine salts such as guanidine nitrate is performed continuously [6] (see Fig. 1).

Dicyandiamide (85 parts) and ammonium nitrate [*6484-52-2*] (180 parts) are mixed and dosed by a screw into a heated stirring vessel where the mixture is melted down. The melt is then run into a cascade of two further vessels where the main reaction occurs. The hot molten mass is subsequently dissolved in mother liquor to give a warm salt solution, which is pumped through a filter (to remove solid triazines) and cooled in a continuously operating crystallizer. The crystallized guanidine nitrate is centrifuged, dried, and stored. This process is conducted on a technical scale for guanidine nitrate, hydrochloride, and sulfamate. The yield of pure salt is normally ca. 90 – 95 %. By solidifying the molten mass on a cooling conveyor belt immediately after it leaves the reaction cascade, a crude product can be obtained containing ca. 91 – 92 % guanidine salt and 3 – 5 % ammonium salt, together with small amounts of dicyandiamide and triazines.

Other processes involve the reaction of dicyandiamide, ammonium salts, and ammonia in aqueous solution or in liquid ammonia under pressure [6]. These processes are not industrially important.

1.2.2. Guanidine Salts from Cyanamide

Cyanamide is used mainly for the production of substituted guanidines (see Chap. 2). For simple guanidine salts, calcium cyanamide [*156-62-7*] is industrially important only in the production of guanidine nitrate [9].

Calcium cyanamide is mixed with mother liquor (from guanidine nitrate crystallization) and concentrated ammonium nitrate solution, and reacted at 120 °C. An aqueous solution of ammonium carbonate [*506-87-6*] is subsequently added to precipitate calcium carbonate. The solids are separated by concentration and filtration. The guanidine nitrate solution is neutralized with nitric acid, freed of precipitated sulfur by filtration, and of noxious gases such as hydrogen sulfide by stripping, and worked up as described above. Although this process gives good yields, it is technically very complicated and thus susceptible to breakdowns.

In modern cyanamide processes an aqueous solution of an ammonium salt and some free ammonia is heated in a stirred autoclave to 120 – 140 °C [10]. Aqueous cyanamide solution is then added slowly, and the reaction is carried out at 0.5 – 1.5 MPa. After being cooled to <100 °C, the solution can be worked up as usual. This method is used particularly to make guanidine salts that cannot be produced efficiently in a fusion process, e.g. guanidine carbonate [95, 96].

1.2.3. Guanidine Salts from Urea

Especially for guanidine nitrate, many attempts have been made to produce guanidines from urea feedstocks because of the cost advantage compared to calcium carbide/calcium cyanamide feedstocks. Melting urea with ammonium nitrate in presence of a silica catalyst at 120-200°C gives guanidine nitrate in high yield according to the following equation [11 – 14]

$$2H_2N{-}CO{-}NH_2 + NH_4NO_3 \rightarrow$$
$$H_2N{-}C(NH){-}NH_2 \cdot HNO_3 + CO_2 + 2NH_3$$

Reaction safety hazard problems, difficulties recycling off-gases and the ammonium nitrate excess, and problems with the re-usage of the spent catalyst have prevented to date from large scale realization of this process.

Guanidine carbonate is formed from urea as a byproduct of some melamine [*108-78-1*] production processes. It can be isolated from the melamine mother liquor by heating (to remove ammonia and carbon dioxide, and precipitate the remaining melamine) and filtering. After further concentration, the liquor is cooled and the crystallized guanidine carbonate is separated [15]. Although the removal of byproducts is rather expensive, significant amounts of guanidine carbonate are isolated in this way by certain melamine producers, mainly to minimize the waste from melamine production which would otherwise have to be burned or buried.

1.2.4. Other Processes

Many processes for the production of guanidine salts are mentioned in the literature: e.g., from urea and carbon disulfide; from urea, sulfur dioxide, and ammonia; from carbon disulfide and ammonia; from carbon dioxide, ammonia, and sulfur dioxide; from ammonium thiocyanate; or from thiourea. None of these methods is used on an industrial scale. For details, see [1, 5 – 8].

Guanidine hydrochloride can be made from cyanogen chloride upon reaction with NH_3 in absence of a solvent at 140-220°C [16]. Guanidine salts of weak acids or anions that do not form stable ammonium salts can be manufactured via the free guanidine base. The latter is prepared by reaction of a suitable guanidine salt with a strong base, whose cation can be precipitated with the anion of the guanidine salt. Such reactions are usually carried out in alcohol solution [17]. To obtain alkali-free guanidine solution, guanidine carbonate or phosphate is reacted in water with calcium hydroxide. After removal of the precipitated salt, the free guanidine base can be isolated by careful vacuum distillation of the solvent. A further possibility is addition of acid or acid anhydride to give the desired guanidine salt. As an example, guanidine silicate is produced in this manner from guanidine carbonate, calcium hydroxide, and amorphous silica [18].

A good way to prepare various guanidine salts of strong or moderate acids, such as stearic acid, in smaller amounts is to react guanidine carbonate with acids or anhydrides. This reaction can be carried out in aqueous solution or by direct mixing and controlled heating of the pure compounds [19].

This method gives guanidine salts of very high purity (depending on the raw materials), because the only byproducts are carbon dioxide and water, which are lost in the vapor.

1.3. Environmental Protection

Apart from the ecological aspects of the production of raw material (e.g., calcium cyanamide), guanidine production itself causes few environmental problems. Ammonia, the only volatile byproduct, must be removed by proper ventilation and burned or recycled. Solid byproducts are mainly nontoxic melamine salts that can be worked up (for applications, see → Melamine and Guanamines), deposited, or burned.

At moderate concentration, guanidine and its common salts are nontoxic to microorganisms, but nitrification is rather slow [20]. Wastewater containing guanidine can therefore best be removed by slow addition to a sewage plant that does not receive too many other nitrogen-containing compounds.

1.4. Quality Specifications

Guanidine salts are normally available in pure (98.5 – 99.5 %) grade as white crystalline substances containing some ammonium salts (0.3 – 0.6 %), triazines (0.2 – 0.4 %), water (0.1 – 0.3 %), and possibly anticaking agent (SiO_2,

0.2 – 0.4 %). Technical grades are also marketed for some purposes as white to yellowish lumps, granules, or powder, with 91 – 96 % guanidine salt, 2 – 5 % ammonium salt, and 1 – 3 % triazines. Some salts are also available as aqueous solutions, e.g., guanidine hydrochloride (60 %), sulfamate, dihydrogen phosphate, or silicate (each 50 %).

High-purity grades for specific applications are available for guanidine thiocyanate and guanidine hydrochloride. For example, solutions of guanidine hydrochloride can be obtained as iron-free (Fe < 0.1 ppm) or low absorbance products ($\varepsilon_{225} < 0.1$).

1.5. Analysis

Nowadays guanidine salts are assayed routinely by cation chromatography with conductivity detection [21]. Besides other methods such as spectroscopic and colorimetric methods, guanidine salts were formerly analyzed gravimetrically by precipitation as the picrate [22].

1.6. Storage and Transportation

Guanidine salts are packed in polypropylene bags, drums with polyethylene lining, or polypropylene big bags. If dry storage is available, guanidine salts can be stored for an unlimited period. Caking of the guanidine salts however can be serious, leading to a single block of product within a few months. Anticaking agent can be added to reduce caking. Solutions must be stored and shipped in plastic or coated steel vessels to avoid corrosion. Cooling of aqueous solutions may cause precipitation of the guanidine salt.

Guanidine nitrate is a dangerous commodity according to transportation regulations and is classified, along with other nitrates, as a substance that has oxidizing and ignitable properties (class 5.1., 22c, UN 1467). For guanidine hydrochloride no declaration is necessary for transport.

1.7. Legal Aspects

Within the European Union, guanidine hydrochloride and guanidine nitrate must be labeled as hazardous substances as follows: guanidine hydrochloride labeled with the hazard symbol X_n (harmful), R 22 (harmful if swallowed), R 36 – 38 (irritating to eyes and skin), S 22 (do not breathe dust); guanidine nitrate is provisionally labeled by the manufacturer with the hazard symbol X_n, R 22, R 36, and S 26.

Guanidine perchlorate [*10308-84-6*] and picrate [*4336-48-5*] are classified in the Federal Republic of Germany as explosives according to the Explosives Act (Sprengstoffgesetz). Handling and storage of these salts are, therefore, subject to special safety regulations prescribed by this act [23] (→ Explosives).

Although the act does not specifically mention pure guanidine nitrate (or nitroguanidine), some mixtures of these substances with other materials (e.g., potassium nitrate, ammonium dichromate, or chlorinated hydrocarbons) are also classified as explosives [23]. The export of guanidine nitrate or nitroguanidine is controlled by special regulations depending on the country of destination.

1.8. Uses

1.8.1. Pharmaceuticals

Guanidine is a valuable intermediate in the synthesis of a variety of pharmaceuticals. Important industrial processes based on guanidine are, for example, the synthesis of sulfonamides such as Sulfaguanidine [*57-67-0*] [24], Sulfamethazine [*57-68-1*] [25], Sulfadiazine [*68-35-9*] [25], and related compounds like Pyrimethamine [*58-14-0*] [26] and Trimethoprim [*738-70-5*] [27]. In addition, purine derivatives such as Triamterene [*396-01-0*] [28], Methotrexate [*59-05-2*] [29], or Folic acid [*59-30-3*] are manufactured from guanidine. More recently, this list of purines, based on guanidine as a building block, has been extended to include commercially available antiviral agents, e.g., Abacavir [*188062-50-2*], Penciclovir [*145839-78-7*] and Retrovir [*256500-90-0*]. Many syntheses involve 2-aminopyrimidines as intermediates. Promising acylguanidine cardioprotectants are synthesized from guanidine salts. Monoacylguanidines, e.g., Cariporide [*159138-80-4*], are effective Na^+/H^+-exchange inhibitors [30]. The guanidine used is generally prepared in situ by reacting salts such as guani-

dine nitrate, hydrochloride, or carbonate with a strong base such as sodium methoxide.

1.8.2. Plant Protection

Guanidine salts are important building blocks for the syntheses of various classes of pesticides. The sulfonylurea herbicides, developed by DuPont, often contain a 2-amino-4,6-dimethoxypyrimidine fragment derived from guanidine. Prominent examples of these active ingredients which inhibit the syntheses of essential amino acids by blocking the enzyme acetolactate synthase are Bensulfuron-methyl [*83055-99-6*] (Dupont) and Halosulfuron-methyl [*100784-20-1*] (Monsanto, Nissan).

Another class of crop-protection agents which are derived from guanidine compounds are the neonicotinoids, which all contain a nitroguanidine fragment. Examples are Imidacloprid [*138261-41-3*] (Bayer), Thiamethoxam [*153719-23-4*] (Syngenta) and Clothianidine [*210880-92-5*] (Takeda, Bayer).

1.8.3. Cosmetics

Guanidine carbonate is used industrially as a nontoxic, highly soluble component of hair care products.

1.8.4. Textile Impregnation, Flame Retardants, Paper and Resin Manufacture

Guanidine hydrochloride is used for textile impregnation as an antistatic agent. Guanidine phosphates are used as flame retardants for cellulosic products like wood, paper, textiles, and laminates. They decompose above 300°C forming noncombustible gases together with polymetaphosphates [31]. The highly soluble primary guanidine phosphate is used for direct impregnation, while the lesser soluble secondary phosphate often is incorporated in, e.g., bonding resins for laminates. Guanidine sulfamate has large-scale application in the manufacture of flame-retardant papers, especially in Japan where paper walls are common. Guanidine stearate is used as an emulsifier and surface-modifying agent in the production of resin coatings and papers.

1.8.5. Propellants and Explosives

Guanidine nitrate is used nowadays in many non-azide formulations for gas generators in automobile airbag applications [32 – 34]. As a constituent of these pyrotechnic mixtures, guanidine nitrate is not regarded as an oxidizer, but as a gas-generating fuel due to its net oxygen demand upon combustion. Guanidine nitrate is used in large amounts to produce nitroguanidine, which is employed widely in the manufacture of propellants and explosives. This process involves the reaction of guanidine nitrate with concentrated sulfuric acid.

Guanidine perchlorate and picrate have been tested as explosives but are of no industrial importance.

1.8.6. Biotechnological Applications of Guanidine Salts

Guanidine hydrochloride and thiocyanate are among the most potent protein denaturants known [35], readily surpassing urea, the other widely employed denaturing agent, in effectiveness for most applications. The physicochemical mechanism involves strong hydrogen bonding to guanidine, modulating structure and solvent properties of water [36]. Their primary application appears to be in the isolation of proteins and enzymes, particularly from genetically modified microorganisms. After successful manipulation of the genetic constitution of a microorganism, the microbial cell begins to produce the protein of interest, which then accumulates in special cellular compartments known as inclusion bodies. To isolate these proteins, they must be released from the inclusion bodies and separated from other cellular constituents.

Traditionally, urea (6 – 9 M) has been used for this purpose, but guanidine salts, particularly the hydrochloride (2 – 6 M), are gaining acceptance as substitutes with distinct advantages [37]. For example, guanidine hydrochloride tends to cause less protein inactivation [37], partly because lower concentrations can be used, compared with urea. Furthermore, guanidine hydrochloride is removed from the extracted protein after denaturing simply by dilution [38]. The use of guanidine salts generally

results in higher yields of extracted protein than is the case with urea.

In addition no protein modification is observed with guanidine hydrochloride as is the case with cyanate present in urea solutions which leads to carbamoylated lysine in the protein of interest.

Furthermore, recombinant Protein A, bound to a chromatography support for immunoaffinity purification of humanized monoclonal antibodies, is effectively regenerated between purification batches (so-called column stripping).

Guanidine salts have attained an unrivaled position in the extraction and purification of biologically active RNA [39, 40], because of their strong denaturing properties. Guanidine thiocyanate is often the salt of choice and is used frequently in combination with, or in place of, phenol for the extraction of RNA [41, 42]. The above-mentioned advantages make guanidine salts particularly attractive for the isolation of substances such as interferons [37, 43], interleukins [44], and the blood factors tissue plasminogen activator (tPA) and urokinase, as well as humanized monoclonal antibodies like Herceptin or ReoPro.

1.9. Economic Aspects

The worldwide production capacity of guanidine salts is estimated to be several tens of thousands of tons per year. This figure includes significant spare capacity for the production of guanidine nitrate. The exact capacity and output of these plants is not known. In most cases, the amount produced is far less than capacity and is used exclusively as captive raw material for the production of nitroguanidine. Apart from this, worldwide annual consumption of guanidine salts is estimated to be several thousands of tons. The main producers are located in Germany and Japan. Smaller amounts are produced in Austria, India, and the People's Republic of China.

2. Derivatives

For Cyanoguanidines (Dicyandiamides) see → Cyanamides, Chap. 3.

2.1. Nitroguanidine [45 – 47]

Nitroguanidine [*556-88-7*], $CH_4N_4O_2$, M_r 104.07, is a very weak base that forms salts only with strong acids. Its solubility in water at 20 °C (100 °C) is 0.27 % (7.6 %). It decomposes at 220 °C.

Nitroguanidine is made by treating guanidine nitrate with concentrated sulfuric acid, fuming nitric acid, or both. The reaction of nitroguanidine with amines gives substituted nitroguanidines [45].

Nitroguanidine (available from Nigu Chemie) is used as a component in triple-based propellants, impact-insensitive military ammunition and as a gas generator in automotive airbag applications [48]. Nitroguanidine is also used in anticorrosive phosphate coatings [49].

2.2. Aminoguanidine [50 – 53]

Aminoguanidine [*79-17-4*], CH_6N_4, M_r 74.09, is a base that forms salts with both inorganic and organic acids [50]. It is soluble in water and ethanol. Preparation of the nitrate [*10308-82-4*], $CH_6N_4 \cdot HNO_3$, involves the risk of explosion [54].

Free aminoguanidine is stable for only a short time; therefore, it is marketed in the form of its stable salts. Commercially, aminoguanidine is offered as the bicarbonate salt [*2582-30-1*], a white powder of usually 99 % assay. The water solubility at room temperature is low (< 5 g/L). It is offered by most world-scale hydrazine producers (→ Hydrazine). Other salts can be prepared from the bicarbonate by reaction with acid.

Aminoguanidine is prepared from hydrazine and aqueous cyanamide solution. Processes based on the reduction of nitroguanidine have no industrial significance.

Uses. Aminoguanidine can act as both a hydrazine and a guanidine derivative; it is particularly suitable for the synthesis of various nitrogen-containing heterocyclic compounds such as pyrazoles, 1,2,4-triazoles, thiadiazoles, tetrazoles, pyrimidines, 1,2,4-triazines, thiadiazoles, and tetrazines [53].

Aminoguanidine salts can be used for removing undesired aldehydes by formation of hydrazones, e.g., in oxidation processes or in polymer syntheses with methacrylic acid.

Cyclization with formic acid produces 3-amino-1,2,4-triazole [*61-82-5*]:

This compound is an important herbicide (Amitrole, ATA), which has a synergistic action with many nonselective herbicides. Some commercially available agrochemicals are based on aminoguanidine, e.g., the fungicide Meferimzone [*89269-64-7*], 4,6-dimethyl-2-[1-(2-methylphenyl)ethylidenehydrazino]-pyrimidinone. 3-Amino-1,2,4-triazole is also used for the preparation of red and yellow cationic triazole dyes such as C.I. Basic Red 22 and C.I. Basic Yellow 25, for poly-(acrylonitrile) fibers (→ Methine Dyes and Pigments). Pharmaceutical applications include Lamotrigine, 3,5-diamino-6-(2,3-dichlorophenyl)-1,2,4-triazine, an anticonvulsant and glutamate inhibitor (Glaxo-Wellcome), and the treatment of type II diabetes with aminoguanidine [56].

Aminoguanidine reacts with nitrous acid in acidic aqueous environment to form 5-amino-(1*H*)-tetrazole [*4418-61-5*] via guanylazide as an intermediate, the former being used a a gas generator, e.g., for automotive airbags [57, 58]. Under neutral pH conditions, diazotization of aminoguanidine leads to 4-(1*H*-tetrazol-5-yl)-1-tetrazene-1-carboxamidine [*539-57-1*], used as a component for shock sensitive explosive primers [59]. Diazotization in glacial acetic acid gives 1,3-di-(tetrazol-5-yl)-triazene [*56929-36-3*] [60].

Salts and derivatives of aminoguanidine are recommended as stabilizers for poly(vinyl chloride), as flame retardants, for coatings of pharmaceutical microspheres and as textile auxiliaries.

2.3. Diamino- and Triaminoguanidine

[51, 52, 61]

Diaminoguanidine. Development of the chemistry of *N,N′*-diaminoguanidine [*4364-78-7*], CH_7N_5, M_r 89.10, has been hampered by the lack of convenient methods for synthesizing it in reasonable purity; a summary of the available methods is given in [52]. In preparing of the hydrochloride [*38360-74-6*] by reaction of hydrazine with cyanogen chloride in a molar ratio of 2 : 1, the formation of byproducts can be suppressed if the reaction is carried out in saturated aqueous sodium chloride solution: yield 71 %, *mp* 170 – 176 °C [62].

Diaminoguanidine is used in the preparation of robenidine [*25875-51-8*], the hydrochloride [*25875-50-7*] of which is an anticoccidial agent for poultry.

Robenidine

Triaminoguanidine. Salts of *N,N′N″*-triaminoguanidine [*2203-24-9*], CH_8N_6, M_r 104.11, are formed by heating the corresponding guanidine salts with hydrazine (molar ratio 1 :

3) in aqueous solution or in alcohol. The triaminoguanidine base can be liberated from its salts by treatment with sodium hydroxide and can be crystallized from aqueous dimethylformamide.

Triaminoguanidine nitrate (TAGN) [*4000-16-2*] is an effective explosive [64]. It is useful as a component of propellants.

2.4. Organoguanidines

A large number of organoguanidine derivatives are known. The many methods of preparation are described in detail in an excellent monograph on carbon dioxide derivatives [65, 66].

The addition of amines, polyamines, hydrazines, or hydroxylamines to cyanamides is one of the most common industrial processes for the synthesis of guanidines. Cyanamide [*420-04-2*] is available as a 50 % aqueous solution or in crystalline form; substituted cyanamides can be obtained from amines and cyanogen chloride (→ Cyanamides).

The classical preparation of guanidines by the action of amines on *S*-alkylisothioureas is versatile and suitable also for the preparation of cyclic compounds. The elimination of alkanethiol byproducts is, however, a disadvantage.

A method for synthesizing di- and trisubstituted guanidines is the reaction of oxidized thioureas with nucleophilic amines [67].

An advanced reagent to produce *N′*,*N″*-bisprotected guanidines from various amines is *N*,*N′*-di-BOC-*N″*-triflylguanidine ("Goodman-reagent", [*207857-15-6*]) [68].

2.4.1. Alkylguanidines

Monosubstituted and *N,N*-disubstituted compounds, including guanidinocarboxylic acids (e.g., creatine [*57-00-1*]), are produced industrially by the reaction of cyanamide with the corresponding amines or aminocarboxylic acids.

Creatine

However, *l*-arginine (→ Amino Acids), the most frequently found guanidino compound in nature, can be best isolated from proteins.

For convenient guanylation (amidination) of primary alkylamines and amino acids without formation of methanethiol, *S*-methylisothiourea sulfate (2 : 1) [*867-44-7*] can be replaced by commercially available *O*-methylisourea sulfate (2 : 1) [*52328-05-9*]. Thus, methylguanidine sulfate (2 : 1) [*598-12-9*] and ethylguanidine sulfate (2 : 1) [*3482-86-8*] are obtained in quantitative yield by the action of methylamine and ethylamine, respectively, on *O*-methylisourea sulfate in aqueous solution at 50 °C:

For steric reasons, *O*-methylisourea salts react preferentially with primary amines and are particularly suitable for selective guanylation of the terminal amino groups of polyamines. *O*-Methylisourea sulfate (available from Degussa AG) is a convenient guanylating agent and is also used on an industrial scale for the synthesis of heterocyclic compounds, e.g., benzimidazole anthelmintics and the antibacterial agents pipemidic acid [*51940-44-4*] and piromidic acid [*19562-30-2*].

Guanidine Bases. Free alkylguanidines are strong bases that are more stable than unsubstituted guanidine.

N,N,N′,N′-Tetramethylguanidine (TMG) [*80-70-6*], $C_5H_{13}N_3$, M_r 115.18, is a stable, unusually strong base, pK_a 13.6 (25 °C), with a free imino group. It is a colorless to light-yellow liquid, miscible with water and common organic solvents: 0.92 g/cm^3 (25 °C), *bp* 160 °C, vapor pressure 0.03 kPa (25 °C). Prepared from cyanogen chloride and dimethylamine in a 1 : 2 molar ratio [69], TMG is used as a polyurethane foam catalyst, in the preparation of pigments for color photography, and in steroid synthesis. It is available from Degussa AG and Lonza.

Undiluted *N,N,N′,N′*-tetramethylguanidine strongly irritates the eyes, skin, and mucous membranes. Its LD_{50} is ca. 850 mg/kg (rat, oral).

Salts of tetramethylguanidine [70] or salts of cyclic, peralkylated guanidines [71] have been proposed as ionic liquids for solvent use in "green" chemical reactions.

Short-Chain Alkylguanidines as Building Blocks in Synthesis. Some monosubstituted and *N,N*-disubstituted derivatives are used as intermediates for the preparation of crop-protecting agents.

Pyrimidines can be prepared by condensation of alkylguanidines with a 1,3-difunctional C_3 fragment. Cyclization of alkylguanidines with 2-alkylacetoacetic acid esters produces fungicidally active 5-alkyl-2-alkylamino-4-hydroxy-6-methylpyrimidines. The systemic fungicides bupirimate [*41483-43-6*] and dimethirimol [*5221-53-4*], developed by ICI, belong to this class of compounds.

N,N-Diethylguanidine [*18240-93-2*] and *N,N*-dimethylguanidine [*6145-42-2*] are used as an N−C−N building block for the pyrimidine insecticides pirimiphos-methyl [*29232-93-7*], pirimiphos-ethyl [*23505-41-1*], and pirimicarb [*23103-98-2*]. Pirimiphos-methyl has proved particularly effective for the control of storage pests.

Biologically Active Compounds. Higher alkylguanidines and polyguanidines, because of their fungicidal and antibacterial action, are economically important as fungicides in agriculture or as antimicrobial agents in disinfectants and industrial biocides [72, 73].

n-Dodecylguanidine acetate [*2439-10-3*], Dodine, used primarily for the control of apple and pear scab, exhibits both protective and curative action. Dodine is also a bacteriostatic agent. Dodecylguanidine derivatives are recommended as effective biocides for controlling biological growth in industrial coolant systems.

Other broad-spectrum microbiocidal uses based on alkylguanidine salts include disinfection, sanitation, preservation, and control of *Desulfovibrio desulfuricans* corrosion [73].

Guazatine, prepared by the guanylation of aliphatic diamines and polyamines, is used for cereal seed dressing. It is also used as a postharvest dip in citrus growing. Guazatine is effective against wood-discoloring fungi and, together with quaternary ammonium compounds, is a constituent of wood preservatives.

Based also on guazatine, contact fungicides were developed which control, e.g., the growth of *Septoria nodorum* in wheat [74].

Iminoctadine triacetate is a broad-spectrum contact fungicide, developed by Dainippon Ink and Chemicals (DIC); the active ingredient is the triacetate salt of 1,1′-[iminobis(octamethylene)]diguanidine [*57520-17-9*]. The product is used in Japan primarily for the control of top fruit (tree fruit) and citrus diseases; in Western Europe, good action has been achieved against leaf spot and glume blotch in winter wheat [75].

Other Uses. Guanidinium salts of unsaturated fatty acids are used as corrosion inhibitors [76]. Alkylguanidines linked to a styrene polymer matrix have been proposed as phosphate scavengers for pharmacological treatment of hyperphosphatemia [77].

2.4.2. Arylguanidines

Monoarylguanidines can be prepared by heating aromatic amine hydrochlorides with

excess cyanamide in aqueous solution. Arylbiguanides are common byproducts. Phenylguanidines can be precipitated from the reaction mixture as a carbonate or bicarbonate salt [78].

Phenylguanidine has found application in the production of pyrimidine fungicides like Cyprodinil [*121552-61-2*] [79], Pyrimethanil [*53112-28-0*] [80], and Mepanipyrim [*110235-47-7*] [81].

From the group of 2-guanidinoanilides with anthelmintic properties, febantel [*58306-30-2*] (Rintal), supplied by Bayer, has emerged as an effective broad-spectrum anthelmintic; it is used to treat nematode infections in domestic animals.

Febantel

The guanidine derivative linogliride fumarate (1 : 1) [*78782-47-5*] is a new oral antidiabetic, developed by McNeil. It can be prepared by the Maryanoff process [67].

Diarylguanidines. *N,N′*-Diphenylguanidine (DPG) [*102-06-7*] and *N,N′*-di-*o*-tolylguanidine (DOTG) [*97-39-2*] are used as vulcanization accelerators. Because of their low activity they do not play a major role as primary accelerators; however, they are very important in combination with other accelerators. Diarylguanidines can be used as secondary accelerators for thiazoles, sulfenamides, thiurams, and dithiocarbamates; the most frequently used combination is with mercapto accelerators. These accelerators and the guanidine produce an extraordinary increase in the degree of cross-linking and the rate of vulcanization; high mechanical values (high tensile stress and elasticity) are achieved. *N,N′*-Diphenylguanidine is the most important of the three guanidines DPG, DOTG, and OTBG (*o*-tolylbiguanide; see Section 2.5).

Both DPG and DOTG are prepared by reaction of cyanogen chloride with aniline or *o*-toluidine, respectively, in a molar ratio of 1 : 2.

Cyclic Derivatives. *N,N′-o*-Phenyleneguanidine [*934-32-7*], 2-aminobenzimidazole, $C_7H_7N_3$, M_r 133.15, *mp* 231 – 232 °C (decomp.), obtained by cyclization of *o*-phenylenediamine with cyanogen chloride or cyanamide, is the nucleus for a number of compounds of economic interest; for a review of 2-aminobenzimidazoles, see [82].

Several 2-(methoxycarbonylamino)benzimidazoles exhibit biological activity. Carbendazim (R = R′ = H) [*10605-21-7*] is an important systemic fungicide, while its derivative Benomyl (R = H, R′R =R CO–NH–C_4H_9) [*17804-35-2*] has been withdrawn from the market recently.

Effective anthelmintics, mainly for veterinary use, are:

Albendazole [*54965-21-8*]	(R = S–C_3H_7, R′ = H)
Fenbendazole [*43210-67-9*]	(R = S–Ph, R′ = H)
Flubendazole [*31430-15-6*]	(R = CO–C_4H_6–p–F, R′ = H)
Mebendazole [*31431-39-7*]	(R = CO–Ph, R′ = H)
Oxfendazole [*53716-50-0*]	(R = SO–Ph, R′ = H)
Oxibendazole [*20559-55-1*]	(R = O–C_3H_7, R′ = H)

Albendazole and flubendazole are also effective against worm infection in humans (→ Anthelmintics, Chap. 3.0.0.0.0.7). Substituted 2-(methoxycarbonylamino)benzimidazoles can be prepared by cycloguanylation of the corresponding *o*-phenylenediamine derivatives with *N*-methoxycarbonyl-*S*-methylisothiourea [*39259-32-0*] or *N*-methoxycarbonyl-*O*-methylisourea [*40943-37-1*].

2.5. Biguanide and Derivatives

Biguanide [*56-03-1*], $C_2H_7N_5$, M_r 101.11, *mp* 130 °C (which decomposes violently at 142 °C), is a moderately strong base (pK_b 2.9). It is readily soluble in water and ethanol, and insoluble in ether, benzene, and chloroform. The free base decomposes gradually in aqueous solution. Biguanide forms stable salts with most acids.

Reviews of methods for the preparation of biguanide can be found in [83, 84]. Biguanide salts are prepared by the fusion of dicyandiamide with ammonium salts. [Dibiguanide – copper(II)] sulfate, $[Cu(C_2H_7N_5)_2]SO_4$, is formed by heating dicyandiamide with ammoniacal copper sulfate solution to 90 – 110 °C in a pressure vessel [85]; it can be converted by decomposition with hot 10 % sulfuric acid or hydrogen sulfide to biguanide sulfate (1 : 1) [*6945-23-9*], $C_2H_7N_5 \cdot H_2SO_4$, or biguanide sulfate (2 : 1) [*49719-55-3*], 2 $C_2H_7N_5 \cdot H_2SO_4$ [85, 86].

Biguanide is used to prepare 6-substituted 2,4-diamino-1,3,5-triazines [84]. The reaction of biguanide with esters to form guanamines is catalyzed by sodium alkoxides.

Biguanides substituted at the N-1 position are obtained by heating dicyandiamide with aliphatic or aromatic amine hydrochlorides in water, higher boiling alcohols, or in a melt reaction.

N-substituted biguanide hydrochlorides have found widespread application in pharmacology. Buformin [*692-13-7*], Phenformin [*114-86-3*] and Metformin [*657-24-9*] are used against type II diabetes, the latter being sold in quantities of more than 1000 tons per year worldwide (→ Antidiabetic Drugs, Chap. 3).

o-Tolylbiguanide (OTBG) [*93-69-6*], $C_9H_{13}N_5$, M_r 191.23, *mp* 144 °C, is used as a vulcanization accelerator in the same manner as the guanidines DPG and DOTG (see Section 2.4.2.). An important use is in the preparation of consumer articles that come in contact with food and drinking water (Recommendation XXI of the German Federal Department of Health). *o*-Tolylbiguanide is also employed as a curing agent with moderate reactivity for color-stable, highly glossy or transparent epoxy resin powder coatings.

The N-1,N-5-disubstituted biguanides can be prepared by addition of amines to substituted cyanoguanidines. A particularly convenient synthesis of N1-alkyl-N-5-aryl biguanides involves heating aliphatic cyanoguanidines with aromatic amine hydrochlorides [87, 88]: the antimalarial drug proguanil [*500-92-5*] is obtained as the hydrochloride [*637-32-1*] (Paludrine) by reaction of isopropyldicyandiamide with 4-chloroaniline hydrochloride in boiling water [87].

Chlorhexidine [*55-56-1*], 1,6-bis(4-chlorophenylbiguanido)hexane, $C_{22}H_{30}Cl_2N_{10}$, M_r 505.45, *mp* 134 °C, is a widely used antiseptic (→ Disinfectants). It can be prepared, for example, from 1,6-hexamethylenebis(dicyandiamide) and 4-chloroaniline hydrochloride [89]. Chlorhexidine is used primarily as its salts (e.g., the dihydrochloride [*3697-42-5*], diacetate [*56-95-1*], and digluconate [*18472-51-0*]) in disinfectants (disinfection of the skin and hands), cosmetics (additive to creams, toothpaste, deodorants, and antiperspirants), and pharmaceutical products (preservative in eyedrops, active substance in wound dressings and antiseptic mouthwashes) [73].

Poly(hexamethylene biguanide) hydrochloride (PHMBG, [*27083-26-7*]) is a broad-spectrum industrial biocide developed by ICI. The most important uses are in surface disinfection in hospitals and the food and beverage

industry, and in the preservation of aqueous systems (i.e., aqueous solutions of organic products, such as cutting oils and domestic cleaning agents) [73]. PHMBG also is used to make up spa water and private swimming pools, where it acts as a flocculant for organic biogenic colloids. Polymeric biguanide hydrochlorides with broad antimicrobial action, very low toxicity, and good skin tolerance are also contained in preservatives for cosmetic formulations.

3. Toxicology and Occupational Health

The guanidino group is low in acute toxicity and is not associated with severe health hazards. No mutagenic, carcinogenic, or teratogenic potential has been demonstrated for guanidine.

Free guanidine and its solutions exhibit strong alkaline reactions. They must therefore be handled like alkali metal hydroxides or alkoxides. Guanidine salts of weak acids (e.g., guanidine silicate) also have alkaline properties. Animal tests (rabbit) show that guanidine hydrochloride is a severe primary skin and eye irritant [7, 90]. In a similar test, guanidine nitrate produced mild to moderate eye irritation [91]. Guanidine hydrochloride and guanidine nitrate did not show sensitizing properties in the Buehler test [92, 93].

Toxicities of some guanidine salts (acute oral LD_{50}, rat) are guanidine hydrochloride 1120 mg/kg, guanidine nitrate 1260 mg/kg, guanidine carbonate 1020 mg/kg, guanidine sulfamate 2334 mg/kg, and guanidine stearate 7500 mg/kg. Further toxicological data for guanidine, its salts, and derivatives can be found in [93, 94].

The toxicological properties of individual guanidine derivatives depend primarily on the type of the substitutents. Commercially available guanidines generally have relatively low toxicity. The following are LD_{50} values (rat, oral) for some derivatives: aminoguanidine bicarbonate >5000 mg/kg; nitroguanidine 4650 mg/kg; *N,N,N′,N′*-tetramethylguanidine ca. 850 mg/kg; *n*-dodecylguanidine acetate 1000 mg/kg; *N,N′*-diphenylguanidine 507 – 850 mg/kg; *o*-tolylbiguanide 1800 mg/kg.

Guanidine derivatives may, however, contain amines as impurities, because amines are used as starting material in the production of guanidines.

With the exception of nitroguanidine, cyanoguanidines, and acylated guanidines, guanidine derivatives are basic; the free bases can cause irritation and corrosion of the skin, eyes, mucous membranes, and respiratory tract. Skin and eye contact with the strong free bases should be avoided. The salts are less irritating than the free bases. Exposure limits (MAK and TLV values) have not been established.

1. Introduction

The element hafnium [*7440-58-6*], Hf, is always found in zirconium ore and is available as a by-product of the production of zirconium metal. The average concentration of hafnium in the earth's crust is estimated at 2.8 – 4.5 ppm. Six isotopes occur naturally: ^{174}Hf (0.16 %), ^{176}Hf (5.2 %), ^{177}Hf (18.6 %), ^{178}Hf (27.1 %), ^{179}Hf (13.7 %), and ^{180}Hf (35.2 %). Hafnium is used principally as a minor alloying element in nickel-based superalloys and as a thermal neutron absorber in nuclear power reactors. Annual world consumption is about 50 t.

2. Physical Properties

Hafnium is a heavy, hard, ductile metal similar in appearance to stainless steel. Although chemically very similar to zirconium, it has several physical differences: hafnium has twice the density of zirconium, a higher phase transition temperature, and a higher melting point. Hafnium also has a high thermal neutron absorption coefficient (1.04×10^{-26} m^2), whereas that for zirconium is very low (1.8×10^{-29} m^2). Some physical properties of hafnium are listed below:

Atomic number	72
Relative atomic mass A_r	178.49
mp	2500 K (2227 °C)
bp	4875 K (4602 °C)
Density	13.31 g/cm^3
Thermal conductivity (298 K)	23.0 W m^{-1} K^{-1}
Coefficient of linear expansion (273 – 1273 K)	5.9×10^{-6} K^{-1}
Specific heat (298 K)	117 J kg^{-1} K^{-1}
Vapor pressure	
(2040 K)	10^{-5} Pa
(2280 K)	10^{-4} Pa
Electrical resistivity (298 K)	3.51×10^{-7} Ω · m
Thermal neutron absorption cross section	1.04×10^{-26} m^2
Crystal structure;	
α-form	hexagonal close-packed (HCP)
β-form	body-centered cubic (BCC)
Temperature of $\alpha-\beta$ transformation	2033 K (1760 °C)

3. Chemical Properties

The ionic radii of hafnium and zirconium are almost identical because of the lanthanide contraction. Both elements exhibit a valence of four. Therefore, the chemistry of hafnium is similar to that of zirconium, and the elements are always found together in nature (see also →Zirconium and Zirconium Compounds).

Elemental hafnium reacts with hydrogen (>250 °C), carbon (>500 °C), and nitrogen

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a12_559

(>900 °C) to form brittle, nonstoichiometric interstitial compounds with metal-like conductivity. In molten salts, hafnium is normally quadrivalent, but in anhydrous molten halide salts, it can be reduced to hafnium(III) and hafnium(II).

In aqueous solution, hafnium is always quadrivalent, with a high coordination number (6, 7, or 8). In dilute acid, hafnium slowly hydrolyzes and polymerizes. Hafnium hydrous oxide precipitates from aqueous solution at ca. pH 2. The only inorganic compounds with significant solubility in neutral or slightly basic aqueous solution are the ammonium – hafnium carbonate and potassium – hafnium carbonate complexes. The tendency for hafnium to form inorganic complexes with anions decreases in the following order: $OH^- > F^- > PO_4^{3-} > CO_3^{2-} > SO_4^{2-} > NO_3^- \approx Cl^- > ClO_4^-$.

Reviews of zirconium chemistry [1,2] are frequently useful for indications of the chemical behavior of hafnium, because of the similarity in chemical properties.

4. Occurrence and Raw Materials

Mineralogically, hafnium is always found with zirconium. Although about 40 known minerals contain these elements, the main commercial sources of zirconium and hafnium are *zircon* [*1490-68-2*] and *baddeleyite*, since they are available as byproducts in the recovery of other minerals. Zircon sand is obtained during the processing of alluvial heavy mineral sands to recover the titanium minerals rutile and ilmenite. Commercially recoverable deposits of these heavy mineral sands are found in China, Malaysia, Thailand, India, Sri Lanka, Australia, South Africa, Madagascar, and the United States. Clean (high quality) zircon contains 64 % zirconium oxide, 34 % silicon dioxide, 1.2 % hafnium dioxide, with the balance including aluminum, iron, phosphorus, rare earths, titanium, uranium, and thorium.

Worldwide, the hafnium content of zircon is usually ca. 2 % of the zirconium content. A notable exception is a Nigerian zircon, available in commercial quantities during 1957 – 1965, that contained 6 % hafnium (based on zirconium). Two minerals, a Norwegian thortveitite and a Mozambiquan hafron, have been reported to contain more hafnium than zirconium. Baddeleyite usually contains hafnium at <2 % of the zirconium content. At the Phalaborwa complex in the Republic of South Africa, baddeleyite is recovered from process tailings in the extraction of copper and the extraction of apatite for phosphate fertilizers.

Although hafnium reserves are significant, demand is low and easily met as a byproduct of the production of reactor-grade zirconium. Known hafnium reserves are listed in Table 1.

5. Production

Processing steps and alternative processes for the production of hafnium metal from zircon sand are shown in Figure 1.

5.1. Ore Cracking

Zircon is a refractory mineral, whose decomposition requires the use of aggressive chemicals and high temperature. Today, the commonly used techniques are caustic fusion, direct carbochlorination, or thermal dissociation; however, other procedures such as fusion with

Table 1. Known hafnium reserves, in 10^3 t

Country	Annual zircon production	Zircon reserve *	Hafnium content of zircon reserve
Australia	480	32 000	390
United States	135	15 000	145
South Africa	135	15 000	145
Brazil	18	4000	38
India	15	9000	85
Sri Lanka	5	3000	29
Malaysia	3	3000	29

* Estimated.

Figure 1. Flow diagram for production of hafnium

dolomite, fusion with potassium hexafluorosilicate, and a two-step process involving carbiding and exothermic chlorination of the crude carbide have all been used extensively to obtain zirconium and hafnium in more chemically active form.

The caustic fusion of zircon by using a slight excess of sodium hydroxide at 600 °C is the most common zircon ore-cracking process [3]:

$$ZrSiO_4 + 4\,NaOH \rightarrow Na_2ZrO_3 + Na_2SiO_3 + 2\,H_2O$$

The cooled reaction mass is broken up and slurried in water, which dissolves sodium silicate and hydrolyzes sodium zirconate to soluble sodium hydroxide and insoluble hydrous zirconia; the latter is recovered by filtering the slurry. Hydrous zirconia is soluble in strong mineral acid; hafnium can be recovered from the primary zirconium stream by ion exchange or liquid – liquid extraction.

Variations of this fusion process involve the use of sodium carbonate at 900 °C or the use of only half the quantity of sodium hydroxide to produce sodium zirconium silicate; the latter is subsequently treated with acid to form a soluble zirconium compound. These fusion processes are used worldwide to produce zirconium oxide, aqueous solutious of zirconium, and water-soluble zirconium compounds.

Fluidized-bed carbochlorination of zircon sand is the ore-decomposition process used by all three hafnium producers in the Western hemisphere: Teledyne Wah Chang Albany, CEZUS Division of Pechiney, and Western Zirconium Division of Westinghouse:

$$ZrSiO_4 + 4\,C + 4\,Cl_2 \xrightarrow{1100\,^\circ C} ZrCl_4 + SiCl_4 + 4\,CO$$

All the reaction products are gases when they leave the chlorinator. Zirconium and hafnium tetrachlorides are recovered as a powder by cooling the gas mixture to 200 °C in a large-volume space condenser. Silicon tetrachloride is then condensed by direct countercurrent contact of the remaining gas mixture with refrigerated (−40 °C) recycled liquid silicon tetrachloride.

Thermal dissociation of zircon in the high temperature of a plasma torch followed by rapid quenching is used to produce intimately mixed crystals of zirconium and silicon oxides. The oxides can be leached countercurrently with sodium hydroxide to yield zirconium oxide and a solution of sodium silicate, or leached with hot strong sulfuric acid to give a zirconium sulfate solution and silica. Both procedures are used by the Z-Tech Corporation Division of ICI.

5.2. Separation of Zirconium

Many well-known methods exist for separating hafnium from zirconium: *ion exchange* with a dilute sulfuric acid eluent [4]; *liquid – liquid extraction* of hafnium from hydrochloric acid solution by a methyl isobutyl ketone – thiocyanic acid solution [5–8]; *distillation* of the mixed binary tetrachlorides at a pressure above the triple point [9]; and *extractive distillation* of hafnium tetrachloride from the mixed tetrachlorides dissolved in a molten halide solvent [10, 11].

Ion exchange is the easiest laboratory procedure. A dilute solution of $Zr(Hf)OCl_2$ is introduced into a bed of strong cation-exchange resin and eluted with 0.25 M sulfuric acid. The eluate contains three components: (1) a small amount of unseparated metal, apparently polymerized, with minimum retention time; (2) a major fraction containing zirconium; and (3) a smaller fraction containing hafnium. A continuously fed rotating cylindrical bed system has been proposed for commercial separation of hafnium and zirconium [4].

Liquid – Liquid Extraction. The methyl isobutyl ketone (MIBK) liquid – liquid extraction is based on an analytical method for determining hafnium [12]. The process was developed at Oak Ridge National Laboratory to obtain hafnium-free zirconium to contain uranium fuel for nuclear-powered submarines. Recovery of hafnium as a byproduct was initiated when uses were found for the hafnium.

The zirconium – hafnium dichloride oxide solution is introduced at the midpoint of a series of countercurrent contact stages in which the organic solvent is MIBK containing thiocyanic acid and the countercurrent aqueous solution is dilute hydrochloric acid. Hafnium is extracted preferentially into the organic solution as a hafnium oxide – thiocyanate complex. The separation factor per stage is 4 – 5. After extrac-

tion, hafnium is recovered by treating the organic phase with dilute sulfuric acid, the water-soluble hafnium sulfate being more stable than the thiocyanate complex. The sulfuric acid is then neutralized to precipitate hydrous hafnium oxide, which is calcined to hafnium oxide. This procedure is used by both U.S. producers of hafnium.

Fractional Distillation. Separation by fractional distillation would be feasible if the tetrachlorides could be handled as liquids; however, the tetrachlorides are solid or gaseous unless kept under pressure while heated to the triple point of zirconium tetrachloride (435 °C, 2.0 MPa). The operating range of a binary distillation system is limited because the critical temperature for zirconium tetrachloride is ca. 505 °C.

Extractive distillation of the mixed tetrachlorides from molten potassium chloroaluminate at atmospheric pressure was developed and used commercially by CEZUS [10, 11]. The crude tetrachloride product from carbochlorination is first purified by sublimation in an atmosphere of nitrogen with 1 – 5 % hydrogen. The purified tetrachloride is then revaporized, and the vapor is introduced continuously above the midpoint of the distillation column. The potassium chloroaluminate solvent, equilibrated with hafnium-rich tetrachloride, is fed into the top of the distillation column, which is maintained at 350 °C. As the solvent cascades down the column it is gradually depleted of the more volatile hafnium tetrachloride, so that zirconium tetrachloride in the solvent reaching the bottom of the column contains <50 ppm of the hafnium compound. The separation factor per stage is 1.4.

The solvent is fed to a boiler where much of the zirconium tetrachloride is vaporized and passed back up the column to become enriched in hafnium. Solvent from the boiler is fed into a stripper where it is treated with nitrogen to remove the remaining zirconium tetrachloride.

The stripped solvent is pumped to an absorber – condenser above the column where the solvent is equilibrated with the hafnium-rich tetrachloride and returned to the top of the distillation column. Unabsorbed hafnium-rich tetrachloride vapor ($HfCl_4$ content 30 – 50 %) is collected in the hafnium condenser. This hafnium-enriched tetrachloride accumulates until it can be reprocessed in the distillation column under different conditions to produce pure hafnium tetrachloride (<1 % $ZrCl_4$).

The degree of separation attained by these various processes is limited only by the number of stages provided in the separation equipment. Zirconium containing <20 ppm hafnium and hafnium containing <50 ppm zirconium have been produced.

5.3. Winning of Metallic Hafnium

Hafnium dioxide from the separation process is converted first into hafnium tetrachloride by fluidized-bed carbochlorination:

$$HfO_2 + C + 2\,Cl_2 \xrightarrow{950\,^\circ C} HfCl_4 + CO_2$$

The recovered hafnium tetrachloride is purified by sublimation in a nitrogen – hydrogen atmosphere to reduce the levels of aluminum, iron, and uranium.

Kroll Process. Hafnium tetrachloride powder is placed in a vertical cylindrical steel retort welded onto a stainless steel-lined steel crucible containing cast ingots of magnesium. The two chambers are connected by a pipe rising through the center of the hafnium tetrachloride charge. The assembled retort is sealed, evacuated, and filled with argon several times to remove traces of air. The retort is lowered into a furnace; the lower section is then heated to 850 °C. Molten magnesium reduces the hafnium tetrachloride vapor as it sublimes out of the upper chamber. After the reaction is complete, the lower crucible contains hafnium metal, magnesium chloride, and excess magnesium. The retort is cooled and unloaded. The stainless steel liner is separated from the reduction mass, and the upper layer of magnesium chloride is physically removed from the hafnium – magnesium metallic regulus. The latter is loaded into a vacuum distillation furnace for removal of magnesium and residual magnesium chloride. As the temperature gradually increases, magnesium sublimes, leaving a skeletal structure of hafnium sponge. Magnesium chloride melts and drains into the cool lower portion of the retort. After the furnace is cooled and the sponge conditioned by slow, controlled exposure

to air, the sponge is removed and placed in an argon atmosphere, where it is broken and chopped into pieces finer than 20 mm.

Electrowinning. Electrowinning of hafnium and zirconium has long been investigated as an alternative to metallothermic reduction. CEZUS produces hafnium by electrolysis of hafnium tetrachloride dissolved in a molten equimolar bath of potassium and sodium chlorides [13]. Hafnium tetrachloride vapor is introduced periodically below the liquid level of the bath to replenish hafnium. The bath contains just enough sodium fluoride to convert dissolved hafnium into the hexafluorohafnate complex.

5.4. Refining

Applications of metallic hafnium require lower oxygen levels than commonly achieved by the Kroll process. Purification is accomplished by the *Van Arkel – de Boer* process, also known as the iodide-bar or crystal-bar process [14, 15]. Hafnium sponge is treated with iodine vapor to form volatile hafnium iodide, which diffuses to an electrically heated hafnium filament. Hafnium iodide dissociates at the filament temperature of 1400 °C, depositing hafnium on the filament and releasing iodine to repeat the diffusion cycle. The hafnium filament slowly grows from a 3-mm wire to a 40-mm crystal-faceted bar. Purification is effective in leaving behind interstitial impurities such as oxygen, carbon, and nitrogen. Metallic impurities generally transport poorly, depending on the behavior of individual iodides, so the hafnium filament is much purer than the sponge.

Electron-beam melting can also be used to purify hafnium. Hafnium is slowly drip-melted into a superheated molten pool under extremely high vacuum. The more volatile metallic impurities and suboxides are boiled off at a much faster rate, relative to the vaporization of hafnium. Two slow melts are standard for hafnium.

Typical impurity levels for Kroll-process hafnium sponge and electrowon hafnium crystals are shown in Table 2, together with the effectiveness of refining sponge by electron-beam melting or the Van Arkel – de Boer process.

6. Environmental Protection

Zircon contains traces of uranium and thorium in solid solution substitutionally and isomorphically in its structure. The retention of these elements and their radioactive decay daughter products are so complete that geological dating of rocks can be conducted by determining the radiological age of the zircon. Conversely, when the zircon structure is destroyed chemically, uranium, thorium, and their daughter products are released. If the attack on zircon is similar to carbochlorination, in which both zirconia and silica are converted to volatile species, the reaction residue may have sufficient concentrations of less volatile radioactive materials for special disposal procedures to be necessary.

Recovery of hafnia and zirconia from the acid solutions of liquid – liquid extraction results

Table 2. Typical impurity levels ∗ for hafnium metal

	Kroll process sponge	Electrowon crystals	Electron-beam melting ingot	Van Arkel–de Boer crystal bar

∗ In parts per million.

in process streams containing ammonium sulfate and ammonium chloride. Ammonia must be recovered for recycling or sale to avoid a heavy biological oxygen demand on effluent-receiving streams. Extreme care must be taken to ensure that hypochlorite scrubbing solutions from chlorination do not come in contact with effluent streams containing traces of thiocyanate because the mixture produces cyanides.

7. Quality Specifications

For wrought hafnium the following U.S. specifications apply: ASTM B 737-84 for Hot-Rolled or Cold-Finished Rod and Wire; ASTM B 776-87 for Hafnium and Hafnium Alloy Strip, Sheet, and Plate; ASTM G 2-88 and G 2 M-88 for Corrosion Testing of Products of Zirconium, Hafnium, and Their Alloys in Water at 680 °F (360 °C, 633 K) or in Steam at 750 °F (400 °C, 673 K); and ASTM C 1076-87 for Nuclear-Grade Hafnium Oxide Pellets.

In the Federal Republic of Germany, VdTüV Material Sheet 463, Hafnium, 05.83, covers wrought hafnium sheet.

Hafnium for alloying purposes is sold in chunk or particulate form, at the particular chemical purity specified by the customer; the zirconium content is particularly important.

8. Analysis

Hafnium is chemically so similar to zirconium that most gravimetric, volumetric, or colorimetric methods of analysis result in a combined hafnium – zirconium determination. Methods that do not require prior separation of hafnium include atomic absorption spectroscopy, emission spectroscopy, plasma emission spectroscopy, mass spectroscopy, X-ray spectroscopy, and neutron activation [16]. Ores and compounds are frequently analyzed by precipitating hafnium and zirconium with mandelic acid [17], igniting the precipitate to give the combined oxides, and determining the relative proportion of each oxide by X-ray or emission spectroscopy.

Many analytical methods for determining impurities in zirconium can also be applied to hafnium [16, 18]. Carbon and sulfur in hafnium are measured by combustion, followed by chromatographic or IR determination of the oxides [16]. Hydrogen is determined by thermal conductivity after hot-vacuum extraction or by fusion of hafnium with a transition metal in an inert atmosphere and subsequent separation by gas chromatography [19, 20].

Simultaneous determination of nitrogen and oxygen is accomplished by a technique similar to that for hydrogen [21, 22]. Nitrogen can also be determined by the Kjeldahl technique [16]. Phosphorus may be determined by visible spectrophotometry using molybdenum blue [16] but can be determined more rapidly by phosphine evolution and flame emission spectroscopy.

Chloride at low level is determined indirectly by precipitation with silver nitrate and determination of the silver by X-ray or atomic absorption spectroscopy. Fluoride and higher levels of chloride can be measured by selective ion electrode techniques [23, 24].

Other impurities are usually determined by emission spectroscopy, either arc – spark [25, 26] or plasma excitation [27, 28]. Many impurities can be determined rapidly and inexpensively. Atomic absorption is frequently used to determine a variety of impurities in hafnium metal and sponge [29].

9. Storage and Transportation

Hafnium metal powder is a flammable solid and should be kept dry, cool, and separate from potential oxidants. Dry hafnium powder, chemically produced, finer than 8.40×10^{-4} m (840 µm, 20 mesh), or mechanically produced, finer than 5.3×10^{-5} m (53 µm, 270 mesh), must have the following warning labels for shipping:

UN no. 2545
United States DOT: Flammable Solid
IATA Dangerous Goods Regulations: Combustible Solid IMDG Code: Combustible Solid

The same hafnium powder, wet, containing at least 25 wt % water, must be labeled as a flammable solid for all shipping and hazard communication purposes (UN no. 1326).

Hafnium powder of the above descriptions, wet or dry, is forbidden on U.S. passenger

aircraft by DOT. Dry hafnium metal powder, mechanically produced, finer than 3×10^{-6} m, or chemically produced, finer than 10×10^{-6} m, is forbidden from all air transportation by IATA.

Although not specifically required, hafnium hydride or hafnium carbide powder should be labeled, handled, and stored in similar fashion.

Hafnium tetrachloride must be shipped as a corrosive solid (UN no. 1759).

10. Uses

The major uses of hafnium involve the metal. The largest use is as an alloying additive (1–2 %) in nickel-based superalloys. These alloys are used in turbine vanes in the combustion zone of jet aircraft engines. Addition of hafnium to some present-generation alloys has raised the allowable service temperature by 50 °C, improving engine efficiency. Hafnium forms stable precipitates at grain boundaries, improving high-temperature creep strength.

The second major use of hafnium is as control-rod material in nuclear reactors. In early reactors, bare hafnium metal in long cruciform shape was used because of the excellent hot-water corrosion resistance, good ductility, and machinability of hafnium, as well as its high thermal neutron absorption cross section. Hafnium clad in stainless steel is now replacing stainless steel-clad silver–indium–cadmium and stainless steel-clad boron carbide in some commercial nuclear power plants.

Hafnium is also used as an alloying element in niobium, tantalum, titanium, molybdenum, and tungsten alloys, as well as some new nickel aluminides.

Hafnium and hafnium–zirconium alloys have been suggested for use in spent nuclear fuel storage racks, and for tanks and piping in spent fuel reprocessing plants because of the neutron absorption capability of hafnium and its resistance to nitric acid. For a while, shredded hafnium foil was used instead of zirconium foil as fuel in some photographic flashbulbs because hafnium provided a higher intrinsic color temperature and a greater light output. Pure hafnium has also been used as the active tip for plasma arc cutting tools.

Hafnium carbide–niobium carbide solid solutions have been used as a replacement for tantalum carbide in steel-cutting grades of cemented carbide tool bits.

Hafnium oxide has been used as a specialized refractory, including thermocouple insulation for short-term use above 2000 °C. Hafnium and hafnium oxide sputtering targets are used for coatings and specialized electronic applications.

Hafnium tetrachloride has been used to prepare hafnium metallocene Ziegler–Natta-type catalysts, which were the first catalysts to provide high yields of high molecular mass isostatic polypropylene [30]. Hafnium tetrafluoride is used in some heavy-metal fluoride glass cladding [31].

11. Economic Aspects

Production of hafnium oxide and hafnium tetrachloride has been steady since 1980, as a result of the leveling off of zirconium metal production for the nuclear energy program. The availability of hafnium still exceeds market demand. Annual Western hemisphere availability is estimated at 80 t, with consumption estimated at 50 t. Hafnium is produced commercially in the United States (Teledyne Wah Chang Albany and Western Zirconium Division of Westinghouse), France (CEZUS Division of Pechiney), and the Soviet Union.

In 1988, hafnium oxide was available at \$ 100/kg; hafnium crystal bar, at \$ 200/kg; and hafnium wrought metal products (plate, sheet, wire, foil), from \$ 250 to \$ 500/kg.

12. Hafnium Compounds

Compounds of hafnium have been studied mostly to develop methods of separating hafnium from zirconium, producing the metal, and comparing properties with similar zirconium compounds. Although the properties of inorganic hafnium and zirconium compounds are generally comparable, differences in chemical behavior become more evident in organometallic compounds.

12.1. Hafnium Borides

Hafnium boride [*12007-23-7*], HfB_2, M_r 200.11, is prepared by carbon reduction of

hafnium oxide and boron carbide, by coreduction of hafnium and boron chlorides with magnesium or hydrogen, or from the elements. It is of interest because it is very refractory. Hafnium dodecaboride, HfB_{12}, has been synthesized by compressing the elements at 1660 °C and 6.5×10^3 MPa.

12.2. Hafnium Tetrahydroborate

Hafnium tetrahydroborate [*25869-93-6*], $Hf(BH_4)_4$, M_r 237.86, is prepared by reaction of hafnium tetrachloride with lithium borohydride in diethyl ether, followed by double sublimation under vacuum at 20 °C [32]. afnium tetrahydroborate is one of the most volatile hafnium compounds known: *mp* 29 °C, *bp* 118 °C, vapor pressure 2 kPa at 25 °C. Its decomposition at ca. 250 °C forms the basis for a low-temperature method of depositing amorphous hafnium diboride films [33].

12.3. Hafnium Carbide

Hafnium carbide [*12069-85-1*], HfC, M_r 190.60, is usually produced by carbothermic reduction of hafnium oxide in an induction-heated graphite-lined vacuum furnace. Hafnium carbide film can be deposited by reaction of hafnium tetrachloride and methane in a hydrogen atmosphere at 900 – 1400 °C. Hafnium carbide is a nonstoichiometric interstitial carbide with carbon atoms at octahedral interstices of the hafnium metal lattice. The hafnium – carbon phase diagram shows that hafnium carbide is single phase within the range 39.5 – 49.5 atom % carbon at 1400 °C [34]. Hafnium carbide is a hard refractory material with metallic conductivity.

12.4. Hafnium Halides

Hafnium tetrafluoride [*13709-52-9*], HfF_4, M_r 254.48, can be made by addition of a stoichiometric amount of hydrofluoric acid to hafnium oxide chloride dissolved in 8 M nitric acid, to precipitate hafnium tetrafluoride monohydrate. The filtered crystals are dried in a stream of anhydrous hydrogen fluoride gas. Alternatively, anhydrous hydrogen fluoride can undergo an exchange reaction with hafnium tetrachloride powder or vapor, or ammonium fluorohafnate can be heated to drive off ammonium fluoride, leaving hafnium tetrafluoride as residue.

Potassium hexafluorohafnate [*16871-86-6*], K_2HfF_6, M_r 370.68, can be crystallized from hafnium fluoride solution by adding a stoichiometric amount of potassium fluoride. The solution should be acidic to minimize hydrolysis. Other alkali metal hexafluorohafnates (Na_2HfF_6 [*16921-79-2*], M_r 338.46; Rb_2HfF_6 [*16962-20-2*], M_r 463.42; and Cs_2HfF_6 [*16919-32-7*], M_r 558.29) and the corresponding ammonium salts can be prepared similarly. With different proportions of alkali fluoride, other salts can be precipitated, including $MHfF_5$, M_3HfF_7, and $M_5Hf_2F_{13}$.

Hafnium tetrachloride [*13499-05-3*], $HfCl_4$, M_r 320.30, is prepared commercially by carbochlorination of hafnium oxide at 900 °C. Chlorination can be carried out with phosgene or carbon tetrachloride at 450 °C. Hafnium tetrachloride is used as starting material for the preparation of organic derivatives of hafnium, alkoxides, and alkali chlorohafnates. The partitioning of mixed tetrachloride vapor by alkali-metal salts, with preferential formation of alkali chlorohafnate and elimination of unreacted zirconium tetrachloride, has been proposed as a means of separating hafnium and zirconium [35, 36]. Hafnium tetrachloride vapor reacts with steam to form finely divided hafnium oxide. Solid hafnium tetrachloride reacts with water to form hafnium oxide chloride and hydrochloric acid. Hafnium dichloride oxide, $HfOCl_2$, is soluble in water and can be crystallized from hydrochloric acid solution as the octahydrate, $HfOCl_2 \cdot 8H_2O$, [*14456-34-9*], M_r 297.52. The solubility of hafnium dichloride oxide increases significantly with temperature and decreases with increasing acidity up to 8.5 M hydrochloric acid. This crystallization procedure is the preferred method for obtaining pure hafnium dichloride oxide prior to the preparation of other hydrated hafnium compounds. Hafnium dichloride oxide is converted to the hydrous oxide $HfO_2 \cdot xH_2O$ on neutralization, at pH 2. On heating, hafnium dichloride oxide first loses water, then slowly releases water and hydrogen chloride, and is converted into granular hafnium oxide.

Hafnium tetrabromide [*13777-22-5*], $HfBr_4$, M_r 498.11 and hafnium tetraiodide [*13777-23-6*], HfI_4, M_r 686.11 are produced by reaction of the respective halogen with hafnium metal in the absence of air above 300 °C. Thermal dissociation of the tetraiodide is employed in the iodide-bar refining process.

Lower valence hafnium halides have been formed by reduction of tetrahalides with aluminum or hafnium in molten aluminum chloride or molten alkali halide baths. Zirconium is more easily reduced; this is the basis of several proposals for the separation of hafnium and zirconium [37,38].

12.5. Hafnium Hydride

Hafnium hydride, HfH_x, is formed as hafnium absorbs hydrogen. The proportion of hydrogen absorbed depends on temperature and hydrogen pressure. Above 500 °C, as hydrogen is absorbed, hafnium changes from hexagonal close-packed metal, to face-centered cubic hydride, and then to face-centered tetragonal hydride as the composition approaches the limiting solubility, with $x = 2$ [39]. At room temperature, hafnium hydride exists as the face-centered cubic form when $x = 1.7 - 1.8$, and as the face-centered tetragonal form when $x \geq 1.87$.

Hafnium hydride is brittle and easily crushed. Crushing must be conducted in an argon atmosphere to avoid ignition of the fine powder. Hydrogen absorption is reversible; the process of hydriding, crushing, and dehydriding is therefore used to convert hafnium metal pieces into powder with little contamination. Hydrogen is removed by heating the hydride under vacuum.

12.6. Hafnium Nitride

Hafnium nitride [*25817-87-2*], HfN, M_r 192.5, is a nonstoichiometric interstitial nitride, which is single phase within the range 42 – 50 atom % nitrogen [40]. Hafnium nitride film can be deposited by reacting hafnium tetrachloride vapor with ammonia or nitrogen in a hydrogen atmosphere above 1000 °C. Above 1400 °C, nitride powder is produced. This film deposition process is used to coat cemented carbide tool bits. Hafnium nitride film is more effective than titanium nitride in reducing frictional forces and wear when machining steel [41].

12.7. Hafnium Dioxide

Hafnium dioxide [*12055-23-1*], hafnia, HfO_2, M_r 210.49, is the only stable oxide of hafnium. It melts at 2900 °C and exists in three solid phases: a monoclinic phase stable up to 1475 – 1600 °C, above which hafnia changes into the tetragonal phase, the stable form up to ca. 2700 °C. Between 2700 and 2900 °C, hafnia has a cubic fluorite structure. Like zirconia, the tetragonal – monoclinic transition is a martensitic transformation that exhibits considerable hysteresis. The cubic structure can be stabilized by addition of calcium oxide, yttrium oxide, or some of the rare-earth oxides, including those of cerium and europium. The use of stabilized hafnia for high-temperature engineered ceramics avoids the catastrophic 7 % shrinkage that accompanies transformation from monoclinic to tetragonal form.

Hafnium dioxide is very stable and, except for strong hydrofluoric acid, is attacked only at elevated temperature. Hafnia reacts with carbon tetrachloride or phosgene above 400 °C, and with chlorine and carbon above 700 °C, to form hafnium tetrachloride. At high temperature, hafnia reacts with many metal oxides to form solid solution oxides or hafnate compounds such as $CaHfO_3$.

12.8. Other Derivatives

Several excellent publications that cover the preparation and properties of hafnium alkoxides, hydrides, and organic derivatives are available [42–44].

13. Toxicology and Occupational Health

Hafnium metal with a high surface area, such as thin machining chips, powder, sponge, or grinding dust, is extremely flammable, even pyrophoric. If the metal is slightly wet (5 – 15 wt %

H_2O) ignition can occur with explosive violence. Fires can be extinguished with a layer of dry salt or with a blanket of argon if the metal is in a container.

Water can be hazardous for fire fighting because it is a source of oxygen for the burning metal. The resulting hydrogen and steam may blow the burning chips throughout the area. Several reviews of methods for safe handling of hafnium and zirconium are available [45,46].

Hafnium is essentially nontoxic. No health problems have been attributed to hafnium in more than 30 years of industrial experience with the metal and its compounds. Toxicological studies of ingestion indicate that the toxicities of hafnium and zirconium are similar. Hafnium was found to accumulate in the liver when hafnium compounds were injected intravenously or intraperitoneally into rats [47]. Chronic feeding of 1 % hafnium tetrachloride to rats for 90 d caused liver damage [48]. The ACGIH TLV–TWA for hafnium is 0.5 mg/m^3.

Hafnium tetrachloride and tetrabromide hydrolyze immediately on contact with water, releasing hydrochloric or hydrobromic acid fumes. These compounds should be handled with proper ventilation and personal protection.

1. Introduction

The term *hair preparations* covers all preparations used on the scalp or scalp hair. The most important of these are cleansing and conditioning products, colorants, hairstyling preparations (setting lotions, hair sprays, hairdressing aids), and permanent-wave preparations. Recent developments in this field should be viewed from several standpoints. Fashion trends have spurred the development of new products such as high-hold hair lacquers and styling gels, as well as dyes with brilliant fashion colors. Toxicological considerations have also become increasingly important.

Economic Aspects. The total worldwide market for personal care and cosmetics in 1996 has been estimated at 114×10^9 €; hair-care products accounted for 29×10^9 €. The geographic structure of the retail hair-care market is given in Table 1. In the hair-care sector, the most important products were care (55 %), styling (23 %), color (18 %), and others, including hair tonics and home perms (4 %). In recent years hair color products showed the strongest growth on a worldwide basis, while styling products grew only moderately.

Table 1. The geographic structure of the retail hair-care market

Europe	38 %
North America	21 %
Latin America	12 %
Africa/Asia/Pacific	29 %

2. The Scalp and Hair

2.1. Structure of the Skin and Hair Growth

Hair is an appendage of the skin that grows in varying density everywhere on the body. In contrast to the fine, barely visible hair (vellus) of the body, the approximately 100 000 – 150 000 scalp and beard hairs are 40 – 100 µm thick and grow roughly 1/3 mm per day [1]. The structure of the skin and a hair follicle are shown in Figure 1. The hair follicle may be anchored up to 3 mm deep in the scalp and has a high rate of cell division. Scalp hair is one of the fastest growing body tissues, and reflects the life history of its owner. Hair analysis (trichogram) is therefore used as a diagnostic tool in medicine and also in forensic investigations [2, 3].

Figure 1. Vertical section through the skin showing a hair follicle

The growth cycle of human hair has three main phases. In the growth (anagen) phase, lasting two to six years, new hair keratin is formed continuously. The death of some cells marks the beginning of a roughly two-week transitional (catagen) phase, followed by a resting (telogen) phase of three to six months, after which the hair falls out. This accounts for a daily loss of some 100 hairs.

Because hairs are linked to the circulatory and nervous systems through their roots, their

growth can be influenced by hormones, nutrition, and drugs [5]. Balding mostly is a clear indication of a hormonally induced disturbance of hair growth. Hair "cures" are often claimed to promote hair growth, but only minoxidil, finasterid, and antiandrogens have been shown to have a temporary hair-restoring effect after topical application [6].

The scalp contains sweat and sebaceous glands, which are located next to the hair roots in the dermis. The secretions of these glands spread over the scalp surface and onto the hair, where they produce the impression of "oily" or "greasy" hair. The cosmetic problem of oily hair probably results not from the overproduction of sebum by the sebaceous glands, but from a change in its rheological properties [7]. The causes of dandruff (pityriasis simplex capillitii) are also unclear, but this condition is often attributed to a disturbance of scalp microflora [8]. For this reason, antidandruff preparations often contain antimicrobial substances such as selenium disulfide or zinc pyrithione.

2.2. Structure of Hair

2.2.1. Morphology

Cells constitute the principal components of a hair (Fig. 2); they undergo two changes in the hair follicle on their way from the root to the scalp surface. Firstly the cell proteins differentiate by chemically changing from an "uncross-linked" state into a conformation cross-linked by the amino acid cystine. Typically, fibrillar keratin proteins are expressed with a partially α-helical structure. These microfibrils, also called intermediate filaments (IF) [10] reside in amorphous matrix proteins (intermediate filament associated proteins, IFAP). Secondly all the cells change their shape. After differentiation into several cell types, the spherical hair-forming cells at the root periphery (*keratinocytes*) become thin, flat *cuticle cells*, whereas the central cells form lines of elongated, spindle-shaped *cortex cells*. In grown-out hair, the cuticle cells are arranged around the cortex cells in the manner of roof tiles. Cortex cells form the bulk of the hair (ca. 80 %). They have a fibrillar structure and are oriented predominantly parallel to the hair axis. The cells occur in two different morphological forms — ortho- and paracortical cells — which differ in their cystine content and solubility [11]. The natural curliness of a hair is discussed to be determined either by the arrangement of these cells or due to the bent shape of the hair follicle. A concentric arrangement of cells was found in straight hair, whereas segmental arrangement gives rise to curly hair [12]. Thick Caucasoid, Mongoloid, and Negroid hair has a central row of vacuole-containing cells termed the *medulla.*

Figure 2. Structure of a hair

All the hair cells are joined by an *intercellular cement.* This cement consists of a continuous phase of proteins and lipoproteins [13] which, together with adjacent membrane lipids, forms the *cell membrane complex.* The cement provides cohesion and gives the hair the appearance of a strong fiber [11, 14]. The composite structure of the hair [15] is continued within the cortex cells by the macrofibrils, which are an association of microfibrils. The latter form a crystalline phase embedded in an amorphous, highly cross-linked protein matrix. The physical behavior of this natural fiber (see also → Wool) can be described in similar terms to other fibrous polymers or composites [16].

The structural components of the hair dictate its cosmetically important properties:

- Luster: cuticle, medulla, melanin, shape
- Color: melanin
- Combability: cuticle
- Feel: cuticle surface, cortex
- Natural wave: cortex, ratio and arrangement of ortho and para cells

- Deformability (temporary set, permanent wave): cortex, microfibrils
- Elasticity, strength: cortex
- Friction: cuticle scales, hair surface geometry
- Hygroscopicity, swelling: cortex
- Electrostatic charging: cuticle surface
- Volume, body: hair thickness and geometry, cortex curliness

Figure 3. Scanning electron micrographs of a normal, smooth hair (A) and a damaged hair (B) with detached cuticle scales

As hair grows (i.e., ages), it experiences increasing wear. It is subject to "weathering" from light, abrasion during washing and brushing (especially when wet), and heating due to the sun or to hair dryers. Weathering results in damage to hair structure in the form of detached cuticle scales, greater surface friction, increased porosity, and decreased elasticity. The cohesiveness of the cortex cells can be weakened so much that the hair end splits [17]. Thus, the hair structure varies from the root to the tip; this fact must be considered in the use of hair preparations. A normal hair is shown in Figure 3 A and a damaged hair in Figure 3 B.

2.2.2. Chemical and Physical Properties

Hair consists of *keratin*; this term comes from the Greek word for horn and was originally used to denote a cornified tissue such as hair, nails, hooves, horn, feathers, or cornea. However, keratin has become more and more difficult to define because the term is used both to denote a structural component of hair (e.g., α-keratinic microfibrils) and to characterize the sulfur-containing cross-linked matrix proteins [18]. All structures composed of keratin are, however, distinguished by insolubility in water and common organic solvents.

Hairs consist of a mixture of proteins, some of which have a characteristic amino acid composition and can be classified into protein families. The protein content of a normal hair at 20 °C and 65 % R.H. is ca. 80 wt %. Further components are ca. 5 wt % internal hair lipid, <1 wt % trace elements and metals, and ca. 14 wt % water [19].

Of the 22 amino acids found in hair protein, the most important is L-cystine [*56-89-3*], a sulfur-containing amino acid (ca. 750 µmol per gram of hair). This compound primarily contributes to the cross-linking and thus the mechanical strength of the fibers.

Hair proteins may be classified as high- or low-sulfur; their characteristics are listed in Table 2 [11, 20], see however [21].

The distribution of individual proteins in hair is not homogeneous. High-sulfur proteins are concentrated in the outer layer of cuticle cells, the exocuticle. These cells thus display greater insolubility and chemical resistance than the cortex; they afford protection against ultraviolet radiation [22] and can also serve as a diffusion barrier [19, p. 231]. In cortex cells, the low-sulfur microfibril proteins (= intermediate filaments) are distributed in a matrix of high-sulfur proteins

Table 2. Characteristics of hair proteins

Property	High-sulfur proteins	Low-sulfur proteins	
M_r	10 000 – 30 000	40 000 – 58 000	
Fraction of total protein	ca. 45 %	ca. 55 %	
State	amorphous	amorphous	α-helical, ca. 50 % crystalline microfibrils of cortex
Location	matrix and outer cuticle	nuclear remnants of cuticle and cortex; cell membrane complex; intermacro-fibrillar material	

(keratin associated proteins), giving a composite structure similar to that of a fiber-reinforced plastic.

More than half of the amino acids in hair have hydrophilic or ionizable side groups. Interactions between these groups lead to the formation of hydrogen bonds and salt bridges, which contribute to the stability of the hair fiber.

The variety of reactive acidic and basic amino acid substituents allows chemical reactions similar to those used in the treatment of wool and animal hair [23]. The number of raw materials available for hair preparations is, however, limited by the following requirements: they must not cause skin reactions; they must be effective below 60 °C and within 30 min; and their reactivity should be so well controlled that irreversible structural damage and hair dissolution are avoided. Hair can be regarded as an ion exchanger (e.g., for components of shampoos, rinses, and conditioners [19, p. 249]) or as a biopolymer whose cross-linking can be partially cleaved by controlled reduction of cystine and then restored. This principle forms the basis of permanent waving — fortunately, very little reaction takes place at the skin surface because skin epidermal keratins contain relatively little cystine.

Additional cross-linking reactions on the hair help to stabilize its structure. Cross-linking agents such as formaldehyde are ruled out for toxicological reasons[23].

Though its fraction is rather low, hair lipids gain more and more attention. Especially an 18-methyleicosanoic acid is analyzed as being responsible for the hydrophobic nature of the hair surface [9, 19].

Of particular importance are the interactions of hair with water [19]. Depending on the atmospheric humidity, hair can absorb up to 30 % of its own weight of water. In an aqueous medium, however, it can take up another 100 %, bound primarily by capillary forces [24, p. 96]. The water content of hair dictates its chemical reactivity as well as most of its physical (especially mechanical) properties. The diameter of hair swells by 16 %, but its length increases by only 1.2 %. The longitudinal mechanical stability, expressed as the modulus of elasticity, decreases by a factor of 2.7, whereas the extensibility increases by roughly one-third. The torsional and flexural strengths in the wet state are low, so that the fiber on the whole is softened. This softening allows hair to be shaped and set with water or by permanent waving; however, it provides poor hold in humid air after a temporary set.

Dry hair holds its set best when it is dried under the atmospheric conditions in which it relaxes after setting. Drying then brings the hair into thermal and moisture equilibrium with its surroundings ([19, p. 133]). Above 150 °C (which is seldom reached in practice), hair becomes overdried; its sorption capacity is lowered, and combing causes increased static charge.

The friction of the hair surface is also influenced strongly by its moisture content. Wet hair has a higher friction coefficient than dry hair. Because of the correlation between hair's surface friction and its combability [19, p. 437ff.], wet hair is more difficult to comb than dry hair.

2.2.3. Natural Hair Color

In addition to keratinocytes (hair-forming cells), the follicle contains a second type of cell, the *melanocyte,* which produces tiny grains of pig-

ment. Initially, these granules (melanosomes) consist primarily of a protein called *melanoprotein.* As the granules mature, the protein binds increasing amounts of the pigment *melanin.* The pigment is formed from the phenolic amino acid tyrosine. Tyrosine is converted to a polymeric structure with indole quinone subunits by enzymatic catalysis (tyrosinases) via several intermediates (3,4-dihydroxyphenylalanine, DOPA). A variety of mesomeric pigment structures with high optical absorption appear to be formed. Melanin granules are transferred from the dendrites (armlike outgrowths) of the melanocytes to the adjacent keratinocytes, probably by phagocytosis. The granules are then transported into the mature hair inside the keratinocytes. Here they are stored in the colorless protein mass of the cortex cells. Melanin granules give hair its natural color.

Nature provides an abundance of hair colors and shades, which result not just from the number, size, and distribution pattern of melanin granules in the hair, but also from the type of melanin [12, 25]. At least two distinct species occur: — brown — black *eumelanin* and yellow – red *phaeomelanin.* Eumelanin is found chiefly in Mongoloid, Negroid, and dark Caucasoid hair; red and blond Caucasoid hair contains chiefly phaeomelanin, with only small amounts of eumelanin.

Phaeomelanin, whose structure is largely unknown, is distinguished from eumelanin [26] by its synthesis via cysteine, its disputed high sulfur and iron contents [26], low molecular mass, size, appearance, and solubility. A polymeric, graphitelike structure has been postulated for eumelanin [27], the characteristics of which could best be determined after enzymatic isolation from hair[28]. The exact correlation of melanin types with naturally occurring hair colors and shades is, however, not understood completely [29]; other "trichochromes" have been proposed as constituents of the melanin in red hair. Attempts have been made to color hair with melanin precursors [30].

Gray hair, a mixture of white and pigmented hair, has a low content of melanin pigments. The reasons for pigment loss in old age include lowered melanin production or a decrease in the number of melanocytes [24, p. 158].

3. Hair Cleansing and Care Preparations

3.1. Shampoos

Shampoos are cosmetic products for cleaning hair and scalp. The word "shampoo" is derived from a Hindi word meaning massage.

Dirt adhering to the hair may consist of unpleasantly smelling skin flakes, sebum, perspiration residues, and dust, but residues of hair sprays, setting lotions, and conditioning agents may also be present. A shampoo should leave hair pliable and lustrous, with a pleasant odor. The hair should not "fly away" and should be clean but not too strongly defatted, easy to untangle and comb, but at the same time easy to manage and style. Decisive factors for the development of modern shampoos are *grooming* (combability and conditioning of the hair) and *mildness* (compatibility with skin, eyes, and mucosa; no burning on the scalp or in the eyes).

Shampoos are the cosmetic products most often applied to the hair. Nearly all modern shampoos are aqueous surfactant preparations. Dry shampoos are of secondary importance. In the developed Western economies, the trend toward daily hair washing is increasing. Accordingly, shampoos are among the most important products in the area of personal grooming (see Table 1).

3.1.1. Composition

3.1.1.1. Surfactants

The principal constituents and most important raw materials of shampoos are surfactants (→ Laundry Detergents; → Surfactants). Their task is to break the physical bonds between dirt and substrate, and to transport dirt into the aqueous medium. As in other fields, the selection of a surfactant or combination of surfactants is dictated by the consumer's association of lathering ability with cleansing power. Surfactants for shampoo must, therefore, satisfy the following requirements: they must have high cleansing power; they must lather well, even in the presence of dirt, sebum, and sweat; and they must be compatible with body tissues as well as environmentally harmless (biodegradable).

These standards are best met by *anionic surfactants. Amphoteric and nonionic surfactants* are also employed in modern shampoos. *Cationic surfactants* play only a secondary role in special-purpose formulations. For comprehensive reviews of surfactants employed in shampoos, see [31 – 33].

The first surfactants used for hair cleansing were *fat soaps.* In hard water, however, these products create a deposit of lime soap on the hair, so their use must be followed by treatment with an organic acid, such as citric or acetic acid. Another drawback is the alkaline pH of soap, which may increase the swelling of hair.

Anionic Surfactants. The most important anionic surfactants for shampoos are alkyl sulfates, alkyl and alkylaryl sulfonates, olefinsulfonates, secondary alkyl sulfonates, alkylaryl sulfates, alkyl ether sulfates, sulfosuccinates, and protein – fatty acid condensates.

Alkyl sulfates are far superior to soaps because they have much lower hardness sensitivity. *Lauryl sulfates* are employed most often, they form a good, stable foam but have a strong defatting action on hair and skin.

The skin compatibility of the alkali salts (sodium lauryl sulfate [*151-21-3*]) is not optimal; for this reason and because of solubility, the ammonium salt [*2235-54-3*], the alkanolammonium salts, or mixtures of lauryl sulfates with gentler surfactants, such as sulfosuccinates, protein – fatty acid condensates, or amphoteric surfactants, are used.

Alkyl and alkylaryl sulfonates are the most important detergents used in household cleansers worldwide. They have a very strong defatting action, and their skin tolerance is no better than that of the alkyl sulfates. The latter can, however, be manufactured in higher purity.

Olefinsulfonates and secondary alkyl sulfonates have not yet found much use. With respect to skin compatibility, they lie between the alkyl sulfates and the alkyl ether sulfates. α-Olefinsulfonates have good foaming properties, even in hard water.

Alkylaryl sulfates are no longer important primarily because of their poor biodegradability.

Alkyl ether sulfates are the most important surfactants, especially in Europe, but also in the United States. They display virtually all the positive qualities sought in a surfactant for use as a shampoo. Alkyl ether sulfates with one to three ethylene oxide units are easy to thicken; they are also easy to use and have good skin compatibility. The magnesium salts of alkyl ether sulfates with an ethoxylation value higher than 3 are especially gentle.

Sulfosuccinate esters (e.g., disodium laureth sulfosuccinate [*39354-45-5*]) and *protein – fatty acid condensates,* such as potassium coco-hydrolyzed animal protein [*68920-65-0*] (i.e., the protein is hydrolyzed and reacted with coconut oil fatty acid chlorides), have been known for a long time and are particularly gentle to the skin. Some drawbacks are their relatively high price and the sensitivity of the ester and amide bonds to hydrolysis. They are used in shampoo only as mixtures with the surfactants already cited.

Amphoteric surfactants used in shampoo can be divided into two classes: (1) the betaines, and (2) the alkyl amphoglycinates and alkyl amphopropionates. The *betaines* (e.g., alkylbetaines and especially alkylamidopropylbetaines such as cocoamidopropylbetaine [*61789-40-0*]) generally have good foaming qualities. Because of their normally more gentle properties, the amidopropyl derivatives are preferred. Betaines are compatible with anionic, cationic, and nonionic surfactants.

The *alkyl amphoglycinates* and *amphopropionates* especially the coco amphocarboxyglycinates [*68650-39-5*] and coco amphocarboxypropionates [*68919-41-5*], are in some cases even more gentle than betaines in terms of compatibility with skin and eye mucosa, but most of them have poorer lathering qualities.

Cationic surfactants have a positive charge and are strongly absorbed by the hair. Because of the problem of residue buildup (especially at acidic pH values), they are not generally suitable for use in shampoo alone and are used in mixtures with anionic surfactants. Only a few special-purpose shampoos, especially those for the treatment of severely damaged hair, contain these compounds.

Nonionic surfactants, with a few exceptions, have poor lathering power. Alkylpolyglucosides such as lauryl polyglucose (lauryl glucoside [*110615-47-9*]) are a new generation of nonionic surfactants used in shampoos. Based

on glucose and fatty alcohols, they have good cleaning and foaming characteristics, are stable over a wide pH range, and have positive ecological and dermatological properties. Other products in use are polysorbates (Polysorbate 20 [*9002-64-5*] and Polysorbate 80 [*9005-65-6*]), and fatty alcohol ethoxylates and polyglycerides, which have especially good lathering ability.

3.1.1.2. Other Constituents

Foam builders are used to improve qualities desired by the consumer, such as creaminess and quantity of lather, and foam stability. The main products are fatty acid mono- and dialkanolamides (e.g., Cocoamide MEA [*68140-00-1*] and Cocoamide DEA [*61791-3.21-9*]).

Refatting agents either reduce the defatting of hair caused by shampoo or are deposited on the hair to refat it. This function is carried out chiefly by the fatty acid mono- and dialkanolamides used as foam builders.

Conditioning additives prevent tangling during combing and brushing of wet hair, and impart a pleasant, smooth feel to the hair after drying. They also reduce static charge, which causes "flyaway hair" on combing and brushing. Products employed for this purpose include cationic polymers (e.g., quaternary hydroxyalkyl celluloses [*53568-66-4*]), silicones, and silicone derivatives. The admixture of amphoteric surfactants, fatty amides, and fatty acid esters to the basic anionic shampoo surfactant can also bring about conditioning effects.

Thickeners must be added to surfactant solutions to prevent the shampoo from running down the face and neck and into the eyes. Salts such as sodium chloride or ammonium chloride are used in combination with amphoteric surfactants, particularly betaines, poly(ethylene glycol) – fatty acid esters, alkanolamides, glycerol – fatty acid monoesters, and polymers such as hydroxyalkyl celluloses and acrylates.

Opacifiers give shampoo a rich, pleasing appearance. Relatively insoluble, higher melting, waxlike substances impart opacity or pearlescence to the shampoo, depending on the crystallization properties. The primary agents are fatty acid alkanolamides, chiefly in mixtures with ethylene glycol monostearate [*111-60-4*] and distearate [*627-83-8*] or cetyl alcohol [*36653-82-4*] and stearyl alcohol [*112-92-5*].

Coloring agents are added to improve the appearance of a shampoo. Only certain agents are allowed by law, see Section 10.2; care must be taken that they do not color the hair.

Ultraviolet absorbers are often required to stabilize dyes against the action of light, especially when the packaging is transparent. Use of these materials is also regulated in many countries.

Fragrances in shampoos mask the characteristic odor of the ingredients and impart a pleasant aroma to washed hair after rinsing. Because these substances often do not form a clear solution in the shampoo base, solubilizers such as highly ethoxylated fatty alcohols must be added. These oils and solubilizers can both greatly affect the viscosity of the product.

Buffers (pH stabilizers) such as citric, tartaric, adipic, and phosphoric acid and their salts are added to adjust the pH of shampoo to a value that is gentle to the skin. They also protect surfactants such as the alkyl ether sulfates against hydrolysis.

Preservatives are required in shampoo because surfactants normally represent a food source for a variety of microorganisms and are thus biodegradable. The use of preservatives is also regulated by law. Both the Federal Republic of Germany and the EC list permissible preservatives, see Section 10.1.

The many possible interactions between shampoo components and preservatives mean that the proper preservative for a given shampoo formulation must be determined by testing.

Other additives are described in Section 3.1.2.

3.1.2. Types of Shampoo

Shampoos can be classified according to the form in which they are supplied, as well as the effects produced by special additives.

Form.

Clear shampoos are used most frequently worldwide. The viscosity of these formulations is adjusted on the basis of practical experience. They are easy and inexpensive to manufacture, and completely satisfy consumer requirements.

Gel shampoos resemble clear shampoos but have a higher viscosity and are normally packaged in tubes. They may, however, be harder to distribute and to rinse out.

Opacified and pearlescent shampoos are more difficult to formulate than clear or gel shampoo. However, they have a richer appearance and can be formulated to contain more special additives because a clear solution is not necessary.

Aerosol shampoos in pressurized packages make even thin liquid formulations convenient to use. However, the packaging is more expensive, so this type of shampoo is seldom seen.

For numerous sample shampoo formulations, see [33 – 36].

Effects of Special Additives (see also Section 3.1.1)**.**

Shampoos for frequent use designed to meet the consumer trend toward daily hair washing and *baby shampoos* are based on especially mild anionic surfactants (e.g., sulfosuccinate esters, magnesium alkyl ether sulfates) or mixtures of anionic, amphoteric, and sometimes nonionic surfactants. With surfactant mixtures, the gentle action on the scalp and hair is due not to the concentration of the surfactants, but to the interaction between surfactants and other ingredients. Baby shampoo should further be formulated so that a burning sensation does not occur when the product comes in contact with the eyes.

Conditioning shampoos must render the hair easy to comb and tangle-free in the wet state, as well as glossy and soft when dry. These shampoos are especially important for dyed or bleached hair and long hair, which is difficult to untangle and comb after washing with simple shampoo. Conditioning effects are provided chiefly through the addition of cationic polymers. The deposition of insoluble polymer – surfactant complexes upon rinsing produces a thin film on the hair. In the wet state this film acts as a lubricant, and on dry hair it prevents static charge and stops hair from "flying" [35, 37, 38]. Addition of amphoteric surfactants or refatting agents can also improve the conditioning qualities of anionic surfactant formulations.

Two-in-one shampoos are a class of conditioning shampoos, containing silicones (dimethicones [*9006-65-9*]) or silicone derivatives (e.g., quaternium 80 [*134737-05-6*]) as additional conditioning agents.

Antidandruff shampoos contain agents that reduce excessive scalp flaking to a normal level. Because all such ingredients have been found to have a fungicidal action against *Phytosporum ovale,* this fungus is probably involved in the formation of dandruff [39, 40].

The most important antidandruff ingredients are zinc pyrithione [*13463-41-7*], Octopirox [*68890-66-4*] (1-hydroxy-4-methyl-6-(2,4,4-trimethylpentyl)-2(1*H*)-pyridone), and Climbazole (Baypival; 1-(4-chlorophenoxy)-1-(1-imidazolyl)-3,3-dimethyl-2-butanone [*38083-17-9*]). Selenium disulfide [*7488-56-4*] is also effective, but in some countries it is allowed only in medicinal products.

Zinc pyrithione

Shampoos for oily hair are used to diminish the excessive production of sebum or limit its distribution on the hair. This can be achieved through an appropriate choice of surfactant or the addition of special ingredients [36].

Special shampoos, lotions, and powders for the treatment of hair lice contain *insecticides,* e.g., 1,2,3,4,5,6-hexachlorocyclohexane [*608-73-1*], pyretrine I [*121-21-1*], pyretrine II [*121-29-1*], malathione [*121-75-5*], piperonyl butoxide [*51-03-6*], and mercury.

Head and body shampoos do not significantly differ from hair shampoos. *Tinting shampoos* are discussed in Section 5.2.4.

3.1.3. Dry Shampoos

Dry shampoos do not contain surfactants; they are powders that absorb sebum and dirt on the hair surface and remove it mechanically. Examples of ingredients are rice starch [*977000-08-0*], cornstarch, mechanical additives such as kieselguhr, [*61790-53-2*], and possibly alkaline substances such as borax or sodium carbonate. Dry shampoos have the advantage of cleaning without disturbing the hairstyle. However, drawbacks such as incomplete cleansing of the hair, soiling of clothes, and leaving residues on the hair have severely limited their importance in

the marketplace. For examples of dry shampoo formulations, see [35, 36].

3.2. Conditioning Agents and Treatments

Hair experiences a variety of influences in the course of its life: climatic effects such as humidity and temperature differences (weathering); exposure to sunlight; washing with products containing surfactants; cosmetic treatment such as bleaching, dyeing, permanent waving, or straightening; and combing or brushing. These processes alter the physical, chemical, and morphological properties of hair [41] as well as its reaction to cosmetic treatments such as dyeing and permanent waving. They lead to perceptible roughening of the hair surface, difficulty in combing, tangling, increased static charge, formation of split ends, and loss of natural luster.

Hair conditioning agents prevent, retard, or mask such changes. Their action is restricted largely to modifying the surface qualities of the hair [42, 43] and making it glossy. Nearly all modern shampoos, permanent wave lotions, setting lotions, and dyes contain conditioning additives that prevent excessive mechanical damage to the hair. This simple type of conditioning is not, however, sufficient for chemically treated or long hair; in such cases a special conditioning treatment is also required.

Conditioning treatments are sold as, e.g., conditioners, rinses, intensive treatments, mousse conditioners, and balms. The earliest conditioning treatments were waxes and oils, which provided lubrication and enhanced luster, as well as acid rinses (vinegar), which counteracted the undesirable deposition of lime soap and the swelling of hair. These early products were then combined with anionic emulsions in rinsable "packs."

An improvement in performance was achieved by the addition of cationic surfactants as emulsifiers. The lubricant action of emulsified fats and waxes is aided by charge neutralization when the cationic surfactant is adsorbed on the anionic surface of the washed hair [19, 43, 44]. In this way, an adherent lubricant coating is produced that consists of the nonpolar portions of the surfactant.

The oil-like substances used are primarily fatty alcohols such as cetylstearyl alcohol [*8005-44-5*]; cationic surfactants include cetyltrimethylammonium chloride [*112-02-7*] (cetrimonium chloride) or alkylamidoamines (e.g., stearamidopropyl dimethylamine [*7651-02-7*]). Cationic polymers [45, 46] (see page 11) can also be used in conditioning treatment, along with special ingredients such as antidandruff additives. Polydimethylsiloxanes and organofunctional silicones [47] are widely used in conditioning agents because of their excellent conditioning properties. Numerous formulations can be found in [34 – 36].

Conditioning treatments are generally made by emulsifying the molten wax phase in the aqueous phase containing the surfactant. When the emulsion is cooled, part of the wax phase crystallizes; thus the viscosity increases and the system becomes more stable [48]. The fatty alcohols and the surfactants form gel systems in which the wax and fat constituents are dispersed. Dilution with water breaks the gel structure and liberates the wax [49 – 51].

The addition of special wax components yields pearlescent preparations. If water-insoluble components are omitted and cationic polymers are added, the formulas obtained are transparent and clear.

Besides the usual highly viscous systems (packs, conditioners) and the less viscous ones (rinses), other product forms such as mousses and spray conditioners (aerosol or pump-spray) are possible [7].

Conditioning treatments are generally rinsed out after they have been allowed to work for a defined time. However, some products with a lower content of active ingredients can be left on the hair without rinsing, so called leave-in treatments/conditioner [52]. Leave-in treatments have become more important because specific market needs/niches are convered by that product type. Examples are products for volumizing hair containing water-soluble polymers to give volume, hair ends fluids for splissed hair containing cationic actives and/or combinations of oils in order to increase the cohesion of split ends.

Beside the raw materials needed for base formulations (cationic compounds, fatty alcohols, etc.) additional actives to achieve specific effects on hair are increasingly important. Examples are

panthenol [53] for moisturizing and strengthening of hair, hydrolyzed proteins [54 – 56] for reducing hair damage or creatine [57] and ascorbic acid [58] for hair strengthening.

Other Hair Conditioning Products. Changes in fashion have meant that *hair creams,* especially for men, have lost much of their commercial importance. These products improve the combability and luster, and help to hold the hairstyle. Creams include oil-in-water and water-in-oil types.

Hair tonics refresh the scalp and serve as simple styling aids. They may also contain disinfectants; soothing, cooling, or hair-growth-promoting ingredients, and anti-oil or antidandruff agents [35].

4. Hairstyling Preparations

Styling preparations help to obtain a desired hairstyle and stabilize it during and after its creation. Tools to achieve the hairstyle are comb, brush, flatting irons, curlers (with and without heat) or simply the hands. Base for styling is usually achieved by a temporary set (see Chap. 6). Styling products may also make hair easier to manage, for example by improving its wet combing or brushing qualities. These products include hair sprays, setting lotions, setting mousses, and restructurants. Newer products developed in response to technology and fashion changes are "styling gels", "wet gels", "gel sprays", "hair waxes", shine products like "shine sprays" or "serums", and different types of emulsion-based products with and without polymers.

Styling preparations generally remain in the hair and are not rinsed out. Their active ingredients are usually dissolved polymers, known as film-forming agents, which are deposited on the hair after the evaporation of a suitable solvent. The stabilization of the hairstyle achieved with setting lotions and mousses is due to stiffening and increased friction between hairs [59]; with hair sprays, to cross-linking in the outermost layer of hair; and with gels and waxes, to adhesion between hairs. These preparations also protect the hairstyle to some degree against the action of moisture; i.e., they counteract the reversibility of the setting process.

4.1. Setting Lotions, Mousses, and Restructurants

Setting lotions and mousses make a hairstyle more durable. They must prevent hair from "flying" away, reduce the amount of charge when it is combed or brushed, improve wet or dry combing, and improve its feel and luster. They must not separate from the hair or form flakes, become tacky or sticky at high humidity, or lather during wet combing (see also [7, 60]). *Setting lotions/mousses for temporary sets* (wave sets) are normally distributed in the hair after it has been washed and toweled dry. After that the hair is brushed and combed while using a blow dryer. In the classic way of use of these lotions/mousses hair is wound on rollers and dried.

Restructurants are setting products with special care qualities; they are especially suitable for badly damaged hair.

Composition. The first preparations comparable to modern setting lotions were aqueous or aqueous – alcoholic solutions or gels of natural substances. Examples are egg white or sugar solutions, plant mucilage (pectins, alginates, carrageenan, karaya gum, tragacanth) [61], and beer. These products simply "glued" the hairs together. They had the drawback of forming opaque, brittle residues on the hair, which created dust during combing or brushing and became sticky in the presence of moisture [62].

Modern setting mousses contain polymers (film-forming agents) [62], solvents surfactants, combability improvers, plasticizers, fragrances, coloring agents, UV stabilizers, preservatives (if necessary), and other special ingredients. For sample formulations, see [35, 36].

Film formers may be nonionic, anionic, or cationic polymers dissolved in water or water – alcohol mixtures.

Nonionic film-forming polymers include polyvinylpyrrolidone [*9003-39-8*], the first polymer employed for this purpose. Its high solubility in a variety of solvents is offset by its hydroscopicity, which causes the film to become tacky when air humidity is high. A substantial improvement was made with vinylpyrrolidone – vinyl acetate copolymers [*25086-89-9*], which form much less tacky films. The moisture sensitivity and hardness can be controlled via the ratio of monomer units.

Other nonionic polymers are copolymers of vinylpyrrolidone and dimethylaminoethyl methacrylate monomers [*30581-59-0*] (CTFA vinylpyrrolidone dimethylaminoethyl methacrylate copolymers), polyvinylcaprolactam [*25189-83-7*] (CTFA polyvinylcaprolactam), or vinylcaprolactam dimethylaminopropyl methacrylate copolymer. Vinylcaprolactam offers a better humidity resistance than vinylpyrrolidone [63 – 66].

Anionic film formers are available in a large variety. Normally they are neutralized with organic amines such as 2-amino-2-methyl-1,3-propanediol (AMPD), 3-amino-2-methylpropanol (AMP), or triisopropanolamine (TIPA). Neutralization makes the polymers more soluble and easier to wash out, and the films become softer. Copolymers of vinylacetate-crotonic acid [*25609-89-6*], of methyl vinyl ether and maleic acid hemiesters [*67724-93-0*], acrylates copolymers, sodium polystyrene sulfonate, terpolymers of vinyl acetate, crotonic acid and vinylneodecanoate [*55353-21-4*], acrylic acid are examples of this polymer class.

Cationic polymers have an affinity for keratin, thus making the hair easier to untangle; they also prevent the accumulation of static charge during combing and brushing. However, because cationic polymers become tacky at high atmospheric humidity, they are usually combined with nonionic or anionic film-forming agents. The most important cationic film-forming polymers are quaternary vinylpyrrolidone – dimethylaminoethyl methacrylate copolymers [*37348-62-2*] (CTFA Polyquaternium 11); vinylpyrrolidone – vinylimidazole copolymers [*29297-55-0*] (CTFA Polyquaternium 16) [67]; cationic hydroxyethyl cellulose [*54351-50-7*] (CTFA Polyquaternium 10); poly(dimethyldiallylammonium chloride) [*26062-79-3*] (CTFA Polyquaternium 6); poly(dimethyldiallylammonium chloride) copolymers [*26590-05-6*] (CTFA Polyquaternium 7); copolymers of hydroxyethyl cellulose and polydimethylallylammonium chloride [*92183-41-0*] (CTFA-Polyquaternium-4), vinylpyrrolidone-vinylimidazolium-methacrylamide terpolymers [*827346-45-2*] (CTFA Polyquaternium 68), vinylcaprolactam vinylpyrrolidone and methylvinylimidazolium methosulfate [*174761-16-1*] (CTFA Polyquaternium 46), vinylpyrrolidone dimethylaminopropyl methacrylamide methacroylaminopropyl lauryldimonium chloride copolymer [*306769-73-3*] (CTFA Polyquaternium 55) and chitosan (obtained from chitin by alkali treatment) or its derivatives [68 – 72].

The *solvents* used are water, ethanol, 2-propanol, and their mixtures [70].

Combability improvers include the cationic film-forming polymers listed above and cationic surfactants such as cetyltrimethylammonium chloride, bromide, or phosphate. Cationic silicones known as amodimethicone are also often used.

Plasticizers enhance the flexibility of films formed on the hair. They include esters such as triethyl citrate, adipates, silicones, and polyglycols.

Other ingredients are *fragrances, coloring agents,* and *UV stabilizers.* The regulations in force in each country must be taken into account in the selection of these substances, see 10.1. The effects of their interactions on product stability are determined by storage tests.

Preservatives are generally required at alcohol contents of <15 wt %.

Antidandruff and anti-oil additives, skin-soothing and moisturizing substances, and plant extracts may also be included.

Foaming agents are cationic surfactants listed above other surfactants that improve foaming are alkylpolyglucosides or highly ethoxylated fatty alcohols. These nonionic surfactants are compatible with all types of film-forming agents and are important for solubilizing fragrances and other water-insoluble additives in purely aqueous systems.

Propellants are hydrocarbons such as propane, butane, isobutane and their mixtures, dimethylether or hydrofluorocarbons as HFC 152a [*75-37-6*].

Organosilicones are a special class of additives. Depending on their structure, they can improve combability, shine, and feel of the hair. Several types of organosilicones are used, e.g., cyclomethicone [*69430-24-6*], amodimethicone, dimethicone, dimethicone copolyols, and phenyltrimethicone [*63148-58-3*].

Formulation. Mousses are usually thin aqueous or aqueous-alcoholic solutions in alumina cans with the abovementioned propel-

lants. The solution/propellant ratio varies between 95:5 and 75:25. The amount of polymers or polymer mixtures varies from 0.5 % – 8 %.

Three types of mousses are the most common: Cationic mousses: Here PQ 11 or PQ 4 are the most often used polymer types. Nonionic/cationic mousses: Mixtures of VP/VA Copolymers combined with cationic polymers such as PQ 16, PQ 4, or chitosan are frequently employed. Anion-based mousses: Here combinations of acrylic acid hemiesters or acrylates copolymers with cationic polymers are often found. Also combinations of VA/crotonic acid copolymer with PVP are in use [68, 72].

Due to legal requirements mousses for the US market are limited in their VOC (volatile organic compounds) content up to 6 % (i.e., hydrocarbons, dimethyl ether, or ethanol are classified as VOCs). For mousses with a higher content of propellants fluorohydrocarbons F 152a is used in combination with hydrocarbons [73].

Nonaerosol mousses have a similar composition as aerosol mousses. Here, the mousse is generated through use of squeeze or pump dispenser with a riddle in the head of the pump. The setting liquid is mixed with air in the head of the pump and dispensed as mousse.

Setting lotions are also marketed as thin, aqueous – alcoholic solutions in single- or multiple-application packages. Depending on intended use, they contain 0.5 – 4 % of polymers or polymer mixtures and up to 50 % alcohol. Setting lotions for waving have a higher polymer content than those for blow-drying. Liquid lotions can also be packaged as aerosol sprays (propellant or pump spray, see page 11). Addition of adsorptive or penetrating dyes to setting lotions/mousses allows simultaneous hair coloring. Tinting and setting lotions or mousses are discussed in Section 5.2.4.

4.2. Hair Sprays

Hair sprays are used to stabilize the hairstyle against wind and humidity, for example. The hair must nonetheless appear natural and must not be sticky even at high humidity. The hair spray must dry quickly; it should also be removed easily by brushing or washing because otherwise, the hair becomes heavy and readily soiled. Removal of the spray must not generate visible dust; i.e., the film must be clear, colorless, and invisible, even on dark hair. After application, the hair must have a pleasant smell, be glossy, and not feel dull. The pressure in the hair spray container must not be so high that it destroys the hair style, but must be high enough to give an acceptably small droplet size, so that the hair spray does not appear "wet."

For general information on cosmetic aerosols, see [61].

Aerosol Sprays. Hair sprays are usually two-phase aerosols; both a liquid and a gaseous phase are present inside the container.

Hair sprays are supposed to have originated from the insecticide bombs developed in the United States during World War II. The propellant was dichlorodifluoromethane, but this gas has a rather high pressure (0.5 MPa at 20 °C). Hair sprays did not become practical until "liquefied" gases with a lower vapor pressure became available. In the container, these gases are present in the liquid state. By virtue of the liquid – gas equilibrium, the pressure remains constant through spraying. As early as 1926 – 1929, however, patent applications in Norway and Germany disclosed methods and devices corresponding to those found in modern hair sprays. Dimethyl ether, methyl chloride, isobutane, and other propellant gases were used [74].

The first hair spray resin was shellac [*9000-59-3*], which was difficult to comb or wash out of the hair. In some cases, hairdressers had to treat the hair several times with alcohol – shampoo – water mixtures.

The most important ingredients in hair spray today are the *concentrate* (film formers, solvents, plasticizers, agents for luster, and fragrances) and the *propellant.* For lists of hair sprays and their formulations, see [7, 34 – 36, 61, 75].

Film-Forming Agents. The film-forming agent shellac was superseded in the early 1950s by polyvinylpyrrolidone, which is easier to remove from the hair. Better results are attained with vinylpyrrolidone – vinyl acetate copolymers (see Section 4.1), the harder, more hydrophobic types being used for hair sprays. Still harder films are possible with the vinyl acetate – crotonic acid copolymers discussed in Section 4.1. The other anionic film formers listed in Section 4.1 can also be employed in hair sprays.

Copolymers of methyl vinyl ether and ethyl maleate [*67724-93-0*] or butyl maleate are used most often in the United States. More recently, acrylates, such as *tert*-butylacrylamide – ethyl acrylate – acrylic acid copolymers [*26062-56-6*], [*83457-27-6*]; acrylate – acrylamide copolymers [*977062-93-3*]; and vinylcaprolactam – vinylpyrrolidone – dimethylaminoethyl methacrylate copolymers have been used [76].

Solvents. Ethanol and 2-propanol are the most important solvents in hair sprays. Acetone is still occasionally used. Methylene chloride (dichloromethane) used to be popular, but it is no longer employed in some countries due to controversy concerning its toxicological properties. The maximum water content in hair spray is limited to about 10 – 15 %, otherwise the hairstyle is impaired by destruction of the temporary set. Other components in the concentrate are fragrances [77], plasticizers, and ingredients used to add luster. The same products are used as in setting lotions (see Section 4.1).

Propellants. For a comprehensive list of propellants and diluents, see [61]. Formerly, the most-common propellants were chlorofluorocarbons (CFCs). These products are nonflammable, chemically inert, and good solvents for virtually all polymers. However, they have a high ozone-depletion potential (ODP).

Therefore, by 1979, controversy over the possible action of chlorofluorocarbons on the earth's ozone layer [78 – 83] led the United States to ban their use. International agreements and national legislation have led to a gradual abandonment of CFCs as propellants worldwide. At present, only negligible quantities of CFCs are still used.

Alternatives are the hydrocarbons propane, butane, isobutane, pentane, and their mixtures. These hydrocarbons are highly flammable and poor solvents [84] for most polymers; special polymers (polyacrylates) that are more readily soluble in organic solvents or cosolvents (e.g. dimethyl ether) must be employed. Dimethyl ether is on a par with hydrocarbons with respect to flammability, but it combines the properties of a solvent and a propellant [85, 86].

Packaging. In contrast to other hair preparations, packaging and packaging technology play an important role for aerosols. Containers are usually made of metal, such as tinplate (sheet steel plated with tin) or aluminum, generally with a protective coat of lacquer on the inside. The other components are the valve and the spray nozzle. The selection of nozzle is crucial for the turbulence and particle size of the spray.

Pump sprays ("nonaerosol" sprays) do not employ a propellant gas; thus the selection of resins is less critical. The energy needed to swirl and atomize the concentrate must be supplied by a pump, which is operated with a finger or through a lever. The ingredients of nonaerosol hair sprays are the same as those of aerosol products, but the propellant content is replaced by additional solvent.

4.3. Other Hairstyling Preparations

4.3.1. Gels

Gels became more and more popular since the 1990s. They consist of the following ingredients:

Thickeners: Synthetic gel builders are poly(acrylic acid) cross-linked with alkyl ethers of pentaerythritol [*9003-01-4*] (CTFA Carbomer), Copolymer of C10-C30 alkyl acrylate and/or acrylic acid methacrylic acid or one of their esters cross-linked with alkyl ethers of sucrose (CTFA Acrylate C10-C30 Alkyl Acrylate Crosspolymer), copolymers of half esters of itaconic acid and Ceteth-20 and one or more monomers of acrylic or methacrylic acid or one of their esters (CTFA: Acrylates/Ceteth-20 Itaconate Copolymer) or copolymer of Beheneth-25 methacrylic ester with acrylic/methacrylic acids or their esters (Acrylates/Beheneth-25 Methacrylate Copolymer). Natural-based gel builders are, e.g., cellulose with hydroxyethyl side chains [*9004-62-6*] (CTFA Hydroxyethylcellulose) or the propylene glycol ether of guar [*39421-75-5*] (CTFA Hydroxypropylguar) [87 – 91].

Solvents, formulation aids and polymers are the same as described in Sections 4.1 and 4.2

Formulation. Thickeners are used in concentration from 0.15 % up to 3 %. The concentration of setting polymers varies between 0.5 % and 10 %. For wet gels moisturizing agents like glycerol, propylglycol or sorbitol are used up to 25 %. Common packaging are polyethylene tubes, dispensers, jars or pump spray bottles for sprayable gels.[94, 95]

4.3.2. Waxes (→ Water)

Waxes are used to form the hairstyle in part or in total. Major components are hydrocarbon waxes such as paraffin wax [*8002-74-2*] (CTFA Paraffin), ceresin [*8001-75-0*] (CTFA Ceresin), ozokerite [*12198-93-5*] (CTFA Ozokerite) but also natural waxes as beeswax [*8006-40-4*] (CTFA Beeswax), carnaúba wax, orange peel wax (CTFA Citrus Aurantium Dulcis (Orange) peel wax) or apple wax (CTFA Pyrus Malus (Apple) peel wax) [92].

Oils of synthetic or natural origin are often used as additives (i.e., paraffin oils, avocado oil, jojoba oil or silicone oils) [90, 93].

Emulsifiers such as the Ceteth-4 triester of phosphoric acid [*119415-05-3*] (CTFA Tricetearetn-4 phosphate), ethoxylated fatty alcohols with ethylene oxide chain length between 15 and 40, i.e., Ceteth-20 [*9004-95-9*] (CTFA Ceteth-20), or Steareth-30 [*9005-00-9*] (CTFA Steareth-30) are added to improve the washout ability of the hydrophobic waxes [60].

Another type of wax components are poly(ethylene glycols) [*25322-68-3*] with higher molecular mass (M_r 400–10 000), for example CTFA PEG-8 – PEG-220. Due the good washout ability of the PEGs no additional emulsifiers are needed. PEGs as main wax components impart mixtures with hydrophobic waxes such as paraffin wax or petrolatum (up to 25 %) still a good washout ability [60, 93].

Formulation. Mixtures of waxes are melted and mixed with other components.

Beside the composition of the wax components also filling temperature and cooling time and temperature can influence hardness of the wax, because these parameters can induce different types of crystallization.

Aerosol-wax, a special application type of waxes, can be achieved by mixing the wax components with volatile hydrocarbons such as pentane, isopentane, isododecane and hydrocarbon propellants. This type of wax can be sprayed on the hair or applied into the hands.

4.3.3. Emulsion-Based Styling Products

There are several product types that are based on emulsions. Since the mid-1990s these products became more and more important especially for professional hairstyling.

4.3.3.1. Creams and Pomades

A special form of cream-type products are gel waxes, that mainly consist of emulsifiers together with oil and wax components.

Polyethoxylated fatty alcohols, short- and long-chain ethoxylated oleyl alcohols such as Oleth-5 [*5353-27-5*] (CTFA Oleth-5), Oleth-20 [*9004-98-2*] (CTFA Oleth-20), and ethoxylated hydrogenated castor oils, i.e., hydrogenated castor oil with 40 ethylene oxide units [*61788-85-0*] (CTFA PEG-40 hydrogenated castor oil) are some of the most common types.

The most commonly used oils are hydrocarbon-based like paraffin oil [*8012-95-1*], [*8020-83-5*, [*8042-47-5*] (CTFA Mineral Oil) and paraffin replacers like the mixed triester of capric and caprylic acid [*65381-09-1*], [*73398-61-5*] (CTFA Caprylic/Capric Triglyceride) or branched higher alcohol such as octyldodecanol [*5333-42-6*] (CTFA Octyldodecanol).

Common preservatives are systems as 1,3-dimethylol-5,5-dimethylhydantoin [*6444-58-0*] (CTFA DMDM Hydantoin), 2-phenoxyethanol [*122-99-6*] (CTFA Phenoxyethanol), benzylic alcohol [*100-51-6*] (CTFA Benzyl Alcohol), or the esters of hydrobenzoic acid with methanol, ethanol, *n*-propanol or *n*-butanol: [*99-76-3*] (CTFA Methylparaben), [*120-47-8*] (CTFA Ethylparaben), [*94-25-7*] (CTFA Butylparaben) [60].

Formulation. Emulsifiers are used in a concentration between 15% and 30 %, oil concentration varies between 10% – 20 %. Emulsifying temperature ideally is above 90 °C to achieve a clear emulsion. Optional raw materials are polymers which to improve level of setting. Type of polymer depends on type of emulsifier used, it always has to be checked which emulsifier/oil system is compatible with the type of polymer. Using lower amounts of emulsifier would lead to classic hairstyling creams.

4.3.3.2. Gums/Puttys

This product type encompasses emulsions from fatty alcohols, waxes and/or oils, emulsifiers and

polymers. The consistency of these products can vary from a soft thin cream to hard rubberlike materials.

Formulation. Major wax components are fatty alcohols, carnaúba wax, ozokerite or ceresin. There is a broad variety of emulsifiers in use. Often used polymers are nonionic types like VP/VA Copolymers, PVP but also amphoteric or anionic polymers are applied.

Often a thickener is incorporated to stabilize the emulsion and/or to improve the texture of the product [60].

4.3.3.3. Serums

Serums are used to improve the shine of the hair but can be also used for preparation of curls or for straightening the hair. Most important components are silicones. Dimethicones of different molecular mass are one major component to influence the viscosity of the products. Phenyltrimethicones improve the shine and improve definition properties. Cyclomethicones but also volatile hydrocarbons and ethanol are used as "solvent" of serum products. Depending to their viscosity the products can be applied via a dispenser pump or as a non aerosol spray to improve shine of the hairstyle.

5. Hair Coloring Preparations

This chapter deals with cosmetic agents used to modify hair color. However, changes due to intervention in biochemical processes (e.g., side effects of medication) are also known [98]. For example, the antimalarial drug chloroquine [*54-05-7*] and the spasmolytic mephenesin [*59-47-2*] brighten hair color. After discontinuation of drug treatment, the hair grows back in its original color. Chemicals such as hydroquinone [*123-31-9*] and its ether derivatives, also inhibit melanin formation [99]. These ways of altering color should not, however, be regarded as cosmetic treatment because of their mechanism of action and potential side effects (allergy, irritation, hair loss).

5.1. Bleaching

Bleaching, blonding, and lightening of human hair involve the irreversible destruction of melanin pigments by oxidation; partial or complete degradation is possible. The degree of lightening is controlled by the type and concentration of oxidant, the temperature, and the duration of treatment. Because melanin degradation also entails modification of the keratin in hair, the maximum possible extent of lightening is limited by hair quality.

Chemistry of Bleaching. The structure and formation of melanin are discussed in Section 2.2.3. Research has shown that the melanin in hair is relatively resistant to reduction and, in acid solution, to oxidation as well. In alkaline hydrogen peroxide, however, the melanin granules are attacked quickly. Evidently the polymer structure is partly destroyed by oxidation, with the formation of carboxyl groups that facilitate dissolution of the granule under alkaline conditions [19, pp. 67 – 79], [100]. If bleaching is complete, a void is left at the site of the melanin granule [101]. Persulfates are generally added to hydrogen peroxide to intensify the bleaching action. Hydrogen peroxide can also be replaced by its addition compound with urea, carbamine peroxohydrate [*124-43-6*]. Other oxidants, such as sodium carbonate peroxohydrate ($2Na_2CO_3 \cdot 3\ H_2O_2$) or sodium peroxoborate tetrahydrate ($NaBO_3 \cdot 4\ H_2O$) have not met with acceptanc; they are only used in speciality products. For a detailed description of peroxide bleaching, see → Bleaching, Chap. 2.2.4.

The undesirable reaction between bleach and the keratin in hair or wool has been well studied [102]. The principal point of attack is the disulfide bond of cystine, which is oxidatively cleaved via a series of intermediates [103]. The main degradation product is cysteic acid, which is responsible for the higher alkali solubility of bleached hair. In addition, hydrogen bonds and ionic bonds can be destroyed by hydrolysis. The hydroxyl and amino side chains of various keratin amino acids offer points of attack for oxidative degradation [7, pp. 216 – 221]. When a strong bleach is used, alteration of the chemical properties of hair also results in modified physical properties: a higher extensibility and thus lower mechanical strength; a rough, strawlike feel when dry; and a spongy feeling when wet.

Because of its higher porosity, hair swells more rapidly in water, a permanent wave can be produced with more dilute solution, and the dyeing behavior is modified.

Photochemical bleaching of hair by sunlight or UV light has also been investigated with regard to bleaching of natural hair color [104, 105] and the damaging properties of light on hair keratin [106, 107].

Bleaches. Bleach consists of an oxidant and a vehicle to prevent the product from running out of the hair. For sample formulations, see [108].

The most intensive bleaching action is achieved with *paste bleaches,* which are prepared before use by mixing hydrogen peroxide solution (6 – 12 vol %) with a bleach powder. The powder consists of a peroxodisulfate, an alkalinizing agent, stabilizers, thickeners, and other additives. Sodium, potassium, or ammonium peroxodisulfate is used. The ammonium salt is most effective; when combined with an alkalinizing component such as sodium carbonate or silicate, ammonia is formed. The base readily penetrates the hair and promotes bleaching. The addition of stabilizers such as sodium pyrophosphate or sodium oxalate [109, 110] retards the decomposition of hydrogen peroxide in the alkaline preparation and thus enhances the bleaching action. The same holds for complexing agents (sequestrants) such as ethylenediaminetetraacetic acid, which hinder decomposition due to traces of heavy metals. Thickening additives include carboxymethyl celluloses, xanthine derivatives, and synthetic polymers. Certain dyes can also be added.

Dusting of bleaching powders has to be prevented to avoid inhalation of peroxosulfates. This can be achieved by :

- Addition of oils to bind fine particles [111]
- Granulation to enlarge particle size [112]
- Formulation of water free oil containing pastes [113]

Other formulations are *cream and gel bleaches*. These consist of an alkaline vehicle in cream or gel form, which is combined with hydrogen peroxide solution. Peroxosulfate is not contained in these bleaches, but can be added as a bleaching powder to reinforce the action. Bleaching powders formulated on the basis of peroxosulfates and water-free hydrogen peroxide addition compounds are activated by mixing with water instead of hydrogen peroxide solution. In view of their market success, this advantage does not compensate for their poor stability.*Setting lotion* and *shampoo* forms are less important; in acidic solution, these have low hydrogen peroxide concentrations and give a weak lightening effect.

In spite of the importance of bleaches in oxidation dyeing, very few technical improvements apart from formulation aspects have occurred in this field. The selective adsorption of metal ions [114], especially of iron(II) salts [115], on melanin has been proposed for gentler bleaching of human hair. This process has achieved no more acceptance than the use of peroxocarboxylic acids or their precursors, which are important as bleaching intensifiers in textile bleaching.

Application. The highly effective paste bleaches are normally prepared just before use and applied with a brush; skin contact is minimized. The products are left to work for up to 60 min; this time can be shortened by heating or by increasing the concentration of hydrogen peroxide. The problem of hair damage must always be considered. After the bleach has been rinsed out, the hair is generally treated with a conditioning product (see Section 3.2). The formation of acid groups during oxidation promotes the adsorption of cationic compounds, which improve the feel and combability of the hair. To prevent "delayed" oxidation, which may result from residual hydrogen peroxide in the hair, antioxidants such as ascorbic or glyoxylic acid may be added to the conditioning agent [116]. If the conditioner is adjusted to an acidic pH, alkali residues are neutralized and the hair swelling is reversed.

5.2. Dyeing

Hair dyeing includes the use of permanent, semipermanent, and temporary dyes. A *permanent dye* lasts through any number of washings as well as permanent waving. A *semipermanent dye* is removed after two to ten washings, and a *temporary dye* is largely eliminated after one washing.

5.2.1. Dyeing with Dye Precursors

The best method of achieving a permanent hair color is the use of oxidation hair dyes. Only with

these dyes can all the requirements, such as adequate color range, masking of white hair, and permanence, be satisfied. The principle of oxidation dyes is over 100 years old [117] and is used in a similar form for dyeing furs (→ Furs, Chap. 4.3). In hair dyeing, however, toxicological considerations are more important. The dyes are produced inside the hairs from colorless precursors by oxidation with hydrogen peroxide in alkaline solution [118]. Given a suitable choice of intermediates, the hair is uniformly colored. The dyes themselves and the kinetics of their formation have been studied intensively [119].

Figure 4. Oxidative formation of hair dyes

Oxidation. A *primary intermediate,* an aromatic para compound, such as a derivative of 1,4-diaminobenzene or of 4-aminophenol, is oxidized to a quinonediimine or quinonemonoimine, respectively. The imine then reacts with a *secondary intermediate* (coupler), which is a meta compound such as a derivative of 1,3-diaminobenzene, 3-aminophenol, or resorcinol (see Fig. 4). Another oxidation step yields an indo, phenazine, or oxazine dye (→ Azine Dyes, Chap. 2.2.7) which is three times the size of the precursors. This size enlargement is largely responsible for fixing the dye in the hair. With the proper choice of substituents, any color from yellow to blue can be obtained [7, pp. 279 – 283], [120]. If one or two primary intermediates are mixed with various (usually three to five) couplers, a range of colors is produced in the hair, giving the desired shade as an overall impression (Fig. 5).

Figure 5. Formation of color using different couplers

Oxidants include hydrogen peroxide or its addition compounds; in special cases, atmospheric oxygen can also be used. Enzyme systems have also been proposed [121]. The alkali used to accelerate dyeing and swelling of the hair is ammonia or, less often, monoethanolamine. Under these conditions, lightening of the natural melanin pigment depends on the concentration of the oxidant and the primary intermediates. Lightening is desirable because it produces a more even background color; the synthetic dye would otherwise give rise to different shades when applied to gray hair as a mixture of naturally pigmented and white hair.

The simultaneous bleaching process also allows hair to be dyed a lighter color; only small amounts of dye intermediates are needed to off-

set the shade produced by bleaching. The degree of lightening is limited; the color corresponds to that obtained by cream bleaching without peroxodisulfate (Section 5.1).

Advances in the field of hair dyeing by oxidation have related mainly to the areas of toxicology and application techniques.

Primary Intermediates. 1,4-Diaminobenzene [*106-50-3*] (*p*-phenylenediamine) has been the main primary intermediate used worldwide for more than a 100 years but has now been largely replaced by 2,5-diaminotoluene [*615-50-9*]. Other primary intermediates are tetraaminopyrimidine and N,N-dialkylated, ring-alkylated, or ring-alkoxylated 1,4-diaminobenzene derivatives [e.g., 2,5-diamino(hydroxyethylbenzene) [*93841-24-8*]]. 4-Aminophenol and its derivatives, such as 4-amino-3-methylphenol [*2835-99-6*], yield red-violet and orange indoanilines and indophenols with the usual couplers; they are therefore important for red shades, whereas diaminopyrazoles and their derivatives [e.g., 1-(2-hydroxyethyl)-4,5-diaminopyrazole [*155601-17-5*]] yield bright red, red violett and orange colors with a broad range of different couplers [122].

Couplers can be classified into three groups according to the color obtained with the aromatic 1,4-diamines: blue, red, and yellow-green couplers.

The usual *blue couplers* are 1,3-diaminobenzene derivatives with the ability to couple at the 2,4-positions relative to the amino groups. Examples in use include *N*- [123] and *O*-hydroxyethyl derivatives [124] dimeric couplers [125], and heterocyclic compounds [126].

The principal *red couplers* are 3-aminophenol [*591-27-5*], 5-amino-2-methylphenol [*2835-95-2*], and 1-naphthol [*90-15-3*]. Among *yellow-green couplers,* resorcinol [*108-46-3*], 4-chlororesorcinol [*95-88-5*], and benzodioxoles should be mentioned, as well as (with restrictions) methylresorcinol derivatives. The importance of the yellow-green couplers lies in the broad-band absorption of the dyes produced, which makes natural-looking hair shades possible. A overview on Combinations of primary intermediates and couplers used in hair colorants is given in Table 3.

Table 3. Combinations of primary intermediates and couplers used in hair colorants

Primary intermediate	Coupler	Color on hair
2,5-Diaminotoluene	*m*-phenylenediamine	blue
2,5-Diaminotoluene	2,4-diaminophenoxyethanol	violet-blue
2,5-Diaminotoluene	*m*-aminophenol	magenta-brown
2,5-Diaminotoluene	5-amino-2-methylphenol	magenta
2,5-Diaminotoluene	1-naphthol	purple
2,5-Diaminotoluene	resorcinol	greenish brown
N,*N*-Bis-(2-hydroxyethyl)-p-phenylenediamine	*m*-phenylenediamine	green-blue
N,*N*-Bis-(2-hydroxyethyl)-p-phenylenediamine	2,4-diaminophenoxyethanol	green-blue
N,*N*-Bis-(2-hydroxyethyl)-p-phenylenediamine	*m*-aminophenol	green-blue
N,*N*-Bis-(2-hydroxyethyl)-p-phenylenediamine	5-amino-2-methylphenol	violet-blue
N,*N*-Bis-(2-hydroxyethyl)-p-phenylenediamine	1-naphthol	blue
N,*N*-Bis-(2-hydroxyethyl)-p-phenylenediamine	resorcinol	greenish brown
4-Amino-3-methylphenol	*m*-phenylenediamine	magenta
4-Amino-3-methylphenol	2,4-diaminophenoxyethanol	magenta
4-Amino-3-methylphenol	*m*-aminophenol	pale orange red
4-Amino-3-methylphenol	5-amino-2-methylphenol	orange red
4-Amino-3-methylphenol	1-naphthol	red
4-Amino-3-methylphenol	resorcinol	yellow-gray
4,5-Diamino-1-hydroxyethyl pyrazole	*m*-phenylenediamine	magenta brown
4,5-Diamino-1-hydroxyethyl pyrazole	2,4-diaminophenoxyethanol	purple-brown
4,5-Diamino-1-hydroxyethyl pyrazole	*m*-aminophenol	bright orange red
4,5-Diamino-1-hydroxyethyl pyrazole	5-amino-2-methylphenol	intense red
4,5-Diamino-1-hydroxyethyl pyrazole	1-naphthol	purple
4,5-Diamino-1-hydroxyethyl pyrazole	resorcinol	red

Other dye intermediates are derivatives of 2-aminophenol [*95-55-6*]. Trihydroxybenzenes, dihydroxyanilines, or diphenylamines are used chiefly in "autooxidative" systems, i.e., systems using oxidation with atmospheric oxygen without an added oxidant. The diphenylamines are oxidized to indo dyes (an overall term including indamine, indoaniline, and indophenol dyes). The oxidation of 1,4-diaminobenzene alone leads to Bandrowski's base, a skin irritant [127]; (→ Azine Dyes, Chap. 2.2.7). Intensive work has been carried out since the first patent appeared [128] to produce indole precursors that mimic the biological melanogene-

sis process. Until now, the performance of these products has been low. For reviews of the patent literature on new intermediates as well as general progress in the field of hair dyeing generally, see [129, 130], [131].

Some nitro dyes (see below) are used in oxidation hair dyes as well, especially for the shading of brilliant (mainly red) fashion colors. However, they need to be stable to the oxidative conditions during use, as well to the oxidants required to stabilize the respective formulation.

Recently some classes of cationic azo-dyes have been found to be also stable under these conditions. These dyes impart brilliance and shine and are mainly used in fashion shades achieving simultaneously high lift [132].

5.2.2. Dyeing with Inorganic Compounds

Permanent hair dyes also include metal salt dyes, which produce a finely dispersed metal deposit on the hair. Metal oxides or sulfides may also be formed; this process can be promoted by the addition of sulfur compounds [7, p. 240]. A metallic gray, brown, or black coloration is obtained depending on the concentration and type of metal ion used.

Metal salts can be used in two ways. First, pretreatment with a trihydroxybenzene compound such as pyrogallol [*87-66-1*] is followed by treatment with an ammoniacal silver salt solution. This allows rapid dyeing due to the formation of metallic silver and oxidation products of the trihydroxybenzene derivative. If pretreatment is performed with thiosulfate instead of a benzene derivative, the process yields unstable silver thiosulfate and finally black silver sulfide.

In the second method, a metal salt solution (silver, lead, or bismuth; less often nickel, cobalt, or manganese) is applied; colloidal sulfur may also be added. "Progressive" coloration is obtained; i.e., the color intensity increases gradually with each treatment. Dyeing is based on (1) the reaction of the metal salts with the added sulfur and the sulfur in the hair keratin, which yields metal sulfides, and (2) the deposition of finely divided metals or metal oxides.

Metal salt dyes are no longer important in professional hairdressing, for three reasons:

1) Their use involves toxicological problems.
2) In permanent-wave neutralization, bleaching, or oxidation dyeing, metal salts catalyze the decomposition of hydrogen peroxide used as oxidant. When the temperature rises, the liberated oxygen can make the hair brittle.
3) The selection of colors is limited, and the shades look metallic and unnatural.

In some countries, certain oxidation dyes may not be used on the lashes and eyebrows, and the above disadvantages of metal salt dyes are of no consequence. In this area, dyes based on silver nitrate are still used [133]. Dyes based on lead and bismuth salts are sold in small quantities as "color restorers."

5.2.3. Dyeing with Direct Dyes

With direct dyes, as opposed to oxidation dyes, the actual dye (and not its precursor) is applied to the hair. It imparts a semipermanent or temporary color that lasts for a variable time. Lightening is not possible.

The first historically known hair dyes were semipermanent ones. The ancient Egyptians and Romans dyed hair and fingernails with henna, which contains lawsone [*83-72-7*] (2-hydroxy-1,4-naphthoquinone), a red-orange dye; walnut shells, containing juglone [*481-39-0*] (5-hydroxy-1,4-naphthoquinone), which gives a yellow-brown color; and indigo [*482-89-3*]. They also employed combinations or mordants with metal salts. To a slight extent, hair is still dyed with henna, juglone, indigo, and extracts such as chamomile (containing apigenin, 4′,5,7-trihydroxyflavone [*520-36-5*], which gives a yellow color). The use of these products is limited, however, because of poor selection of shades, uneven coloring, and laborious method of application [7, pp. 236 – 241].

Nearly all the chromophore systems common in dye chemistry (nitro, azo, anthraquinone, triphenylmethane, and azomethine) are currently used [35, pp. 526 – 533], [131]. Disperse dyes, cationic (basic) dyes, and anionic (acidic) dyes are employed.

Nitro Dyes. Nitro dyes are the most important class of direct hair dyes; they are substituted derivatives of nitrobenzene or nitrodiphenylamine (→ Nitro and Nitroso Dyes). By proper selection of donor groups and substitution site on the benzene ring, a spectrum of dyes

from yellow to blue violet can be prepared [7, pp. 247 – 250], [134] (see Fig. 6).

Figure 6. Influence of substituents on the color of nitro dyes

Nitro dyes are special because the small dye molecules penetrate the hair and impart color throughout the hair or in an annular pattern [135]. In this way, intense colors can be obtained even in hair with a large proportion of white. The dyes are not, however, fixed in the hair by size enlargement or ionic bonds (as in oxidation dyes), and so they slowly wash out.

The physical and chemical properties of dyes are very important for even coloring. First a hair dye should have comparable affinities for the roots, damaged areas, and tips. Second, the combined yellow-to-blue dyes used for shading must have similar properties so that color shifts will not take place when the hair is washed, for example. The importance of these problems is illustrated by the number of patent applications disclosing new, "custom-tailored" dyes [129] and suitable dye mixtures [136]. The relatively good colorfastness and stability of some nitro dyes allow them to be used in oxidation hair dyes as well, especially for the shading of brilliant (mainly red) fashion colors.

Cationic (basic) dyes such as methyl violet [*8004-87-3*] or methylene blue [*61-73-4*] are used in rinses; cationic azine or azo dyes are also used in tints. Their molecular size and charge prevent them from penetrating the hair, so that the color pattern in cross section is annular [118]. The charge on the dyes, however, leads to a relatively stable ionic bonding of the dye to acid groups of the hair, which lasts through several washings.

Anionic (acidic) dyes, usually azo dyes, are employed only in special cases. Because the skin is more basic than the hair, these dyes are adsorbed preferentially by the skin, so that contact with the dyeing product leads to severe scalp staining. For this reason, the mainly anionic food colorings are not employed as hair dyes. Attempts to mitigate these disadvantages by using appropriate vehicles (see Section 5.2.4.) have not been successful.

Disperse dyes of the azo and anthraquinone types, on the other hand, are used in hair tints. They also give annular color patterns, which are relatively durable because of the poor solubility of the dyes in aqueous systems. They can be combined with other classes of dyes.

Other Dyes. Metal complex dyes are of minor importance (→ Metal-Complex Dyes). They can be used as such or can be formed on the hair, although the metal salt treatment entails problems (see Section 5.2.2). Brilliant fashion colors (pink, green, etc.) are mostly obtained with anionic dyes, that are often food colorants. Other methods for dye formation in situ [137] or with reactive dyes have not been accepted because of toxicological concerns.

5.2.4. Product Forms

The dyes discussed in Sections 5.2.1, 5.2.2, and 5.2.3 can be used in a variety of coloring products [138] and forms. Many proposed formulations for the preparations discussed below can be found in [108, pp. 526 – 577, 649 – 676] and a more application-related review is given in [139].

Color rinses represent the simplest way of altering hair color. The hair is rinsed with a dilute aqueous or aqueous – alcoholic dye solution. The dyes are generally cationic and are adsorbed by the hair surface; they can mask the yellow color that results from bleaching or, given the proper selection of shade, can impart an attractive accent to the hair. Because of the short contact time with the hair, only slight color changes are possible.

The same holds for *colored or tint setting lotions* (see Section 4.1) that contain added dyes

(usually cationic, disperse, and/or nitro dyes). When the setting lotion is applied, the hair is tinted slightly. The colored film-forming polymers remaining on the hair also contribute to color impression. Changes are limited to refreshing the color, masking individual white hairs, and producing color effects as well as silver or gray shades in white or graying hair.

More pronounced color changes are possible with *tints.* Tints are formulated with direct dyes; intense colors can be obtained, especially with nitro dyes. Contents of 10 – 50 % white hair can be masked, depending on the type of dye used. Appropriate shading can produce fashionable colors or extreme color effects, especially with bleached streaks.

Depending on the desired coloring effect, tints are left on the head for 3 – 20 min. Therefore, thickened products are generally employed. In *foam tints,* a surfactant solution is dispensed as a foam from an aerosol. The foam is distributed easily and does not run off the head. Tints can also be thickened with cellulose derivatives, natural mucilage, or synthetic polymers. Concentrated solutions with intense coloring action can be obtained by using cosolvents (e.g., alcohols and ethylene glycol ethers) and vehicles (e.g., urea derivatives or benzyl alcohol). In *emulsion tints,* the dye base consists of an emulsion.

Permanent hair colors can be achieved with *tint shampoos.* The shampoo base is adjusted to an alkaline pH and contains oxidation dye intermediates. Before application, it is mixed with hydrogen peroxide or a hydrogen peroxide addition compound. In comparison with oxidation hair dyes, tint shampoos employ lower concentrations of base and oxidant. This suppresses the simultaneous bleaching process that occurs during dyeing (Section 5.2.1). As a result, damage to the keratin in hair is diminished, but the uniform coloring action is lost.

Early *oxidation hair dyes* were used in solution form; these have been replaced by cream- or gel-based formulas. The oil-in-water emulsions commonly used can be supplemented with auxiliary ingredients, such as polymers to improve combing ability, as well as other conditioning additives. Extensive patent literature is available on this point [129]. Gel formulations may be based on alcoholic solutions of nonionic surfactants or fatty acid alkanolamide solutions, which form a gel when mixed with the oxidant. The type (emulsion or gel) and the basic composition of the preparation strongly influence dyeing [140]. Different base formulations with the same dye content yield varying color depths and shading due to the distribution of the dye between the different phases of the product, interaction with surfactants, and diffusion from the product into the hair.

For use, the preparation is mixed with the oxidant and applied with a brush or squeeze applicator to the hair, first to the roots and then to the shafts. After a total contact time of ca. 30 min at room temperature, the hair is rinsed and washed, then treated as in bleaching.

In addition to cream and gel formulations, *powder hair dyes* are also marketed but to a lesser extent. Besides the dye intermediates, they contain thickeners and oxidants in powder form. They are stirred with water before use.

5.2.5. Testing Hair Dyes

New dyes and formulations must be tested for toxicological acceptability (see Chap. 10), and hair dyes must also meet a number of conditions related to their end use.

Color can be assessed by colorimetry [141]. The limits of precision are set by the substrate on which the measurement is performed. Studies on test subjects are difficult because of the uneven natural hair color and the background color (i.e., of the scalp). Tresses are hard to prepare at a constant quality level. Measurements on wool cloth give reproducible results, but for oxidation dyes the shades are not identical to those produced on hair. Colorimetric methods are therefore useful only for comparative measurements on the same object, for example, in lightfastness tests. Because hair must be redyed after four to six weeks due to growth, the fastness required of hair dyes is generally less than that needed for textiles. However, stability is still a problem with many indo dyes (see Section 5.2.1). Some of them "fade" even in the absence of light; others exhibit poor light- [142], sweat-, or acidfastness [143]. Results on the lightfastness of nitro dyes appear in [144]. The washfastness of dyes is also important [130, 145], as is wear resistance, especially for colored tints and setting lotions.

5.2.6. Dye-Removal Preparations

The complete removal of oxidation hair colors is a problem that has not yet been solved. Older, more intense dyes, in particular, cannot be removed entirely. Special reductive dye-removal products, mostly based on sulfites, reduce indo dyes to the leuco bases (diphenylamines), which are easier to remove by washing. The process has two deficiencies: it is not complete and the remaining diphenylamine is reoxidized. Oxidation treatment (bleaching) is, therefore, often used for the removal of dyes.

Recently mixtures of reducing agents (e.g., ascorbic acid, sulfites and/or cysteic acid) together with organic acids have been described [146], which may be used for the complete removal of a wide range of oxidation dyes.

Metal salt dyes cannot be removed with these preparations because of the catalytic decomposition of hydrogen peroxide.

Direct dye tints can be removed by washing with shampoo (the rate of removal depending on the type of dye) or, in some cases, by rubbing the hair with ethanol.

6. Waving

Besides cutting and coloring, perming is still one of the most important services at a hairdressing salon. Home permanent waving is not very frequent. Usership shows great geographical variance: the straighter the prevailing hair type, the higher the percentage of women using perms. While in the Latin countries in Europe this percentage is relatively low at ca. 40 %, it is significantly higher in central and northern Europe ($>$ 50 %), and in Japan, the biggest hairdressing market after the United States, it reaches almost 80 %. In 2004 the worldwide market volume totaled $811 \cdot 10^6$ €, in Germany, in comparison, it reached $72 \cdot 10^6$ €.

6.1. Principles and Methods

The principle of hair waving is closely related to the chemical structure of the hair. In waving, both intermolecular and intramolecular bonds are broken and then reformed after shaping. This process involves hydrogen bonds, and salt bridges, disulfide bonds, and hydrophobic and van der Waals interactions between the individual amino acids [7], [19][147 – 149].

Hair was originally waved with curling irons. Here, plastic deformation (heat, water) is based on hydrolytic cleavage of the disulfide bridges in the hair keratin. The London hairdresser K. L. Nessler first produced a "hot permanent wave" in 1906, using heated tongs, spiral curlers pointing away from the head, and an aqueous alkali solution. Lanthionine groups were created that permanently stabilized the shape of the hair keratin [150] (in lanthionine, the – S – S – bridge of cystine is replaced by an – S – bridge). In 1932, Clark and Speakman introduced sulfitolytic cleavage of the cystine bridges with alkaline sulfite solutions. When the solution is washed out, most of the cystine bridges are automatically restored. The mercaptan-based cold-wave preparations now in use were first described in a 1941 patent application by the New York firm of Sales Affiliates [151].

For *temporary waving* (setting) of hair without chemical agents, the keratin is softened by water absorption; the hair loses its original shape, chiefly through the dissolution of hydrogen bonds. If the wet, softened hair is put into a new shape (e.g., on rollers), this shape is retained after drying until the hair is again destabilized by moisture.

Permanent waving can only be achieved through the reduction of cystine; ca. 25 % of the cystine bridges are reduced to cysteine. After the hair has been reshaped, this reaction is reversed with an oxidant [152].

Waving preparations cause changes in the chemical and physical properties of hair. For example, some mercaptans used as reducing agents are bond to hair by thioacetylation [153]. The lanthionine formed during the reduction (softening) phase and the methionine of the hair are partly oxidized to sulfoxides and sulfones during the oxidation (hardening) step [150]. The ability of the hair to be reshaped is markedly diminished by repeated treatment.

The conventional cold-wave process proceeds as follows. The hair is washed and dried with a towel. It is then premoistened treated with a prelotion to equalize different hair structures; wound on curlers ca. 5 – 15 mm in diameter; thoroughly moistened with ca. 50 – 100 mL of the reducing *waving lotion;* left for ca. 10 –

30 min; and then thoroughly rinsed with water. Next, the hair is treated with a *neutralizer* (ca. 50 – 100 mL), which has an oxidizing action; this agent is allowed to act for ca. 5 – 10 min and the curlers are removed. If necessary, neutralization is continued for ca. 5 min more, with 20 – 50 mL of neutralizer. After the neutralizer has been rinsed out, a conditioning treatment (see Section 3.2) can be applied before the hair is finally styled [154].

6.2. Permanent-Wave Preparations

6.2.1. Waving Preparations

Reducing Agents. Since the late 1950s, most waving preparations have used salts of thioglycolic (mercaptoacetic) acid as the principal reducing agents. Glycerol monothioglycolate (GMT) and cysteamine (2-mercaptoethylamine) are still used in several countries in spite of certain toxicological problems. Reducing agents used less commonly are cysteine, 2-mercaptopropionic acid (thiolactic acid), and sulfite. 3-Mercaptopropionic acid, thioglycolic acid hydrazide, and thioglycerol are no longer used because of physiological problems.

Quality criteria for reducing agents are

1) Physiological tolerance (toxicity, sensitization, etc.),
2) Reducing action,
3) Shelf life,
4) Odor,
5) Purity of commercial grades, and
6) Availability and price

Thioglycolate [*68-11-1*] rates highly in all these areas and is, therefore, widely used as a reducing agent. To avoid hazard to skin and hair, the concentration of active ingredients is generally limited by law (see page 38).

Glycerol monothioglycolate [*30618-84-9*] is highly effective in all pH ranges, because of its low pK_a (SH) value. Its drawbacks are that the ester is readily saponifiable (special packaging is required), it has a somewhat greater risk of sensitization.

Cysteine [*52-90-4*] is a reducing agent with a weak waving action; a comparatively high pH (ca. 9 – 9.5) is needed to activate it. Cysteine is highly sensitive to oxidation, and cystine is produced during the waving process. Cystine is poorly soluble in water and forms a white precipitate that is difficult to eliminate. For ways of avoiding this, see [155].

2-Mercaptopropionic acid [*79-42-5*] is slightly less effective in waving than thioglycolic acid; it has a particularly unpleasant odor. *2-Mercaptoethylamine* [*60-23-1*] has similar waving properties to those of thioglycolic acid, but is more sensitive to oxidation and can cause an empyreumatic smell on the hair. Like cysteine, 2-mercaptoethylamine is expensive and is, therefore often employed merely as an additive [156, 157].

Sulfite [*7757-83-7*] (sodium or ammonium salts) does not have such an unpleasant odor as the mercaptans. In the useful pH range 6 – 8, however, added carriers are needed. Sulfite makes hair markedly harder to comb. It also lightens the hair slightly and, with oxidation-dyed hair, causes a relatively great loss of color. Various partial remedies have been proposed to counteract these drawbacks [157, 158].

Alkalinizing Additives. The content of reducing agent (ca. 5 – 11 wt % for thioglycolic acid) and the pH control the waving efficiency of a preparation. However, effectiveness is also strongly influenced by both the type and the quantity of base used for alkalinization [153]. Ammonia and monoethanolamine are most effective in promoting waving action; a combination of ammonium hydrogen carbonate and ammonium carbonate is also effective. Basic amino acids (e.g., lysine) counteract the waving action significantly. With a combination of urea and the enzyme urease, alkalinization increases during processing due to ammonia formation [159].

Other Additives.

Surfactants are included in waving preparations to ensure wettability, but they are also combined with cationic resins in waving lotions or neutralizers to improve wet combing [160]. In permanent-wave foams, the type and concentration of surfactant are especially critical for skin compatibility.

Fragrances are needed to mask the characteristic mercaptan odor. They are usually solubilized with nonionic surfactants (emulsifiers). The fragrances must be inert to the reducing agent used and must also be stable against alkali. A variety of substances have been suggested

for reducing the characteristic mercaptan odor [161].

Combability improvers are primarily cationic polymers, e.g., poly(dimethyldiallylammonium chloride) [*26062-79-3*], or cationic surfactants, e.g., cetyltrimethylammonium chloride [*112-02-7*].

Thickeners. Cellulose derivatives, polyacrylate salts, and other products are used for thickening to a gel consistency. Thickening generally lowers the availability of active ingredients and makes the preparation more difficult to process (oiliness, poor rinsability). Some degree of thickening is, however, often desirable to allow reliable measuring in use and to prevent dripping [162].

Thickened products in cream form are difficult to handle and have technical disadvantages similar to those of gels. They are used only in special preparations [163].

Opacifiers include polymer dispersions, e.g., styrene – vinylpyrollidone copolymers [*25086-29-7*].

Coloring agents give a pleasant appearance but can also serve as an identifying feature. They must be permitted by law and must be stable against reducing agents.

Carriers enhance the effectiveness of the product. Urea is used frequently, as are ethanol and 2-propanol. Other substances, most of them protected by patents, are known [164].

Complexing agents are added to products containing thioglycolates to prevent intensive red-violet coloring due to ferrous and ferric ions.

Finished Products. Waving preparations are sold as aqueous, clear, or opaque solutions, as formulations thickened to gels or creams, and also as aerosol foam permanent waves. For sample formulations, see [150, 165, 166]. The preparations differ chiefly in pH.

Acidic and neutral permanent-wave preparations (pH < 8) contain glycerol monothioglycolate as their most common active ingredient. Since the early 1970s, these products have become more important in Europe and especially in the United States. Because hair swells relatively little at about pH 7, these preparations are particularly gentle. They make hair easy to comb and leave it with a pleasant feel. The danger of overwaving is slight. Drawbacks are the slightly longer application time, an odor somewhat more unpleasant than that of mildly alkaline permanent-wave processes, a possible lack of durability of the wave, and the more expensive packaging (GMT must be packaged separately). However, because of an increasing number of allergic responses toward these acidic permanent-wave preparations since 1990, the consumption of these preparation dropped in the EU.

Mildly alkaline permanent-wave preparations (pH 8.0 – 9.0) are the most commonly used products. Alkalinization is achieved with bases such as ammonia and ammonium hydrogencarbonate or ammonium carbonate, or monoethanolamine.

The preparations are distinguished by good skin compatibility, strong and durable waving, simple packaging, and short application times. They are markedly less suitable for split hair than acidic preparations and, if allowed to act for too long, can easily produce overwaving.

Alkaline permanent-wave preparations are the oldest form of cold-wave preparations. They are alkalinized with ammonia (ca. 0.5 – 1.5 wt %) to a pH of ca. 9 – 9.5. Because of their strong odor (ammonia) and the frequent occurrence of skin inflammation, these products were largely superseded by mildly alkaline formulations in the mid-1960s.

Special preparations include thermally controlled, two-phase, enzyme-based, and foam permanent-wave preparations [154] [166].

Manufacture. Demineralized water is used in the manufacture of permanent-wave preparations. The production plant should be made largely of plastic or glass to prevent contamination of the product with iron. To prevent the buildup of nickel, the use of stainless steel should be restricted to the filling unit, because nickel allergies represent an increasing problem in the hairdressing trade.

Packaging. Preparations should be packaged in plastic materials with low oxygen permeabilities, such as poly(vinyl chloride) (PVC) or poly(ethylene terephthalate) (PET). The free air volume should be as small as possible because the vacuum created by the reaction of atmospheric oxygen can easily deform the packaging.

6.2.2. Neutralizers

The following commercially available oxidizing agents are used as neutralizers:

1) *hydrogen peroxide:* the concentration of commercial aqueous solutions is roughly 0.5 –3.0 wt % hydrogen peroxide, pH 2.0 – 4.5;
2) *potassium and sodium bromates:* the concentration of commercial aqueous solutions is roughly 6 – 12 wt %, pH 6.0 – 8.5;

The most widely used preparations are those containing hydrogen peroxide. Hydrogen peroxide has the advantages of physiological safety (it is degraded by catalases), excellent environmental compatibility, low solution concentrations, and good availability. However, metal salt impurities (iron, copper, and manganese ions) catalyze the decomposition of hydrogen peroxide. Even when such ions are absent or are complexed, hydrogen peroxide solutions still must be stabilized. Inorganic phosphates, salicylic acid, and 4-acetaminophenol are used for this purpose.

Bromate-based neutralizers are employed mainly in Asia because they do not greatly lighten dark hair. At present, aerosol foam neutralizers are also based on bromate because no suitable coating is yet available for protecting aerosol cans against hydrogen peroxide formulations. Bromate has the advantage of being insensitive to metal salt impurities.

Auxiliary ingredients in neutralizers must often be stable not only to oxidizing agents but also to acids. This fact is the primary restriction on the selection of coloring agents and fragrances.

Application Forms. The most common form is the "foam neutralizer," which is applied to the curlers with a sponge and lathered into a foam. Thickening to a stable gel is much more difficult with peroxide-based preparations than with the waving products, because the cellulose derivatives and other polymers are decomposed by oxidation. For ways of overcoming this problem, see [167].

Packaging. Bromate-based products can be packaged in a number of plastics such as poly(vinyl chloride), polyethylene, and polypropylene, whereas only polyethylene is suitable for products containing hydrogen peroxide.

6.2.3. Notes on Use

The prerequisite for a good wave is proper assessment of hair quality; this provides the basis for choosing a preparation and selecting the application time. However, assessment is not simple because even hair that has not been chemically treated exhibits progressive environmental damage from root to tip (see Section 2.2.1). Furthermore, hair on top of the head is subject to more severe weathering (sunlight, humidity) than neck hair; its porosity is thus higher. Chemical treatment (permanent waving, dyeing, or bleaching) also renders the hair more porous [168].

As damage to hair increases, the strength of the preparation used must be reduced and the application time shortened. By supplying heat (drying hood, 50 – 55 °C), the application time can be shortened by 30 – 60 %. The desired wave is controlled by the number and diameter of rollers used. The durability of the wave is generally better in strong, unfrayed hair than in frayed or thin hair.

7. Hair Straightening Preparations

Preparations similar to those employed for permanent waving can be used to straighten naturally wavy or curly hair. However, hair straightening products are usually gels or creams rather than lotions. They contain strong bases such as alkali hydroxides (ca. 1.5 – 4.0 wt % LiOH, NaOH) and other active ingredients such as guanidinium hydroxide [169] or tetraalkylammonium hydroxides [170].

Lye-based products have a stronger action and do not require oxidative posttreatment. However, improper use can easily make the hair brittle, and skin burns may even occur. To reduce these dangers, formulations have a high content of mineral oil.

Thickened preparations are applied to the hair with a brush and distributed through the hair with a comb. The hair is straightened by further combing. The preparations are allowed to work for a predetermined time (ca. 2 – 15 min) and then thoroughly rinsed out. Products containing reducing agents are subsequently treated with a neutralizer, which is completely rinsed out after

ca. 10 min. For sample formulations, see [36, pp. 590 – 591], [171, pp. 581 – 586], [172].

8. Hair Removal

The removal of hair has been practiced for several millenia. Quicklime, gum resin, hot ash, and scrapers were formerly used to eliminate unwanted hair from the arms, legs, armpits, and face. A wider variety of more pleasant methods is now available.

8.1. Epilation and Permanent Hair Removal

Epilation denotes hair removal by physical methods. The following methods are common:

1) Cutting the hairs with a razor, knife, or scissors: hair is quickly eliminated for a period of about two days.
2) Abrading the hairs with pumice or emery paper: this rather painful method is often preceded by an oxidation treatment to weaken the hairs.
3) Pulling the hairs with tweezers or an adhesive: only small amounts of hair can be removed with tweezers. For larger areas, adhesives such as warm or cold wax preparations are employed. The hairs are entangled in an adhesive mass (e.g., resin-wax mixtures) that is attached to a flexible backing. A quick pull tears out the hairs. However, hair grows back after this treatment.

Permanent hair removal is possible by electrolytic destruction of the hair papillae with a d.c. epilating needle or by thermal coagulation of the protein in the hair follicle (diathermy).

8.2. Depilation

Depilatories are chemically active preparations for hair removal. They usually contain a reducing agent and a strong base; both reductive and hydrolytic cleavage of the hair keratin take place between pH 11 and 12.5. Because of the high alkalinity, damage to the horny layer of the skin may occur. The principal chemicals used formerly were alkali and alkaline-earth sulfides, strontium sulfide being the most suitable. Because hydrolysis of sulfides yields the unpleasantly smelling hydrogen sulfide, these agents have been replaced almost completely by thiol salts. The lithium, calcium, or strontium salts of thioglycolic acid or thiolactic acid, in combination with calcium or strontium hydroxide as an alkalinizing agent, are currently found in almost every commercial product. Preparations containing stannite, titanate, and keratinase are often mentioned in the literature [171, pp. 142 – 150] but have no practical importance .

Thickening and moisturizing ingredients include alginates, cellulose derivatives, poly(vinyl alcohol), casein, sorbitol, glycerol, and propylene glycol. Carbonates, zinc oxide, clay, mineral oil, talc, and other substances are employed as fillers. The most widely used form is cream; aerosol foams are also commercially available. Suitable cream bases include stearyl alcohol, cetostearyl alcohol and oleocetyl alcohol ethoxylate. α-Bisabolol, allantoin, and lanolin derivatives are added to protect the skin. A layer of cream about 1 mm thick is applied to the area to be depilated with a spatula. After ca. 5 – 10 min, the spatula is again used to remove the cream and the hair from the skin surface. After the skin has been rinsed thoroughly, posttreatment with vaseline or a slightly acidic cream is recommended.

For further information and sample formulations, see [36, pp. 591 – 597], [153, pp. 449 – 450], [171, pp. 142 – 155], [172].

8.3. Shaving Aids

In wet shaving, *preshave preparations* carry out the following functions:

1) lubrication to allow easier sliding of the razor blade;
2) swelling of the keratin to lower the resistance of hairs to cutting; and
3) desensitization of oversensitive skin.

Many forms are available, ranging from simple shaving creams (superfatted oil-in-water emulsion) to shaving foams, soaps, and products that dispense heated shaving foam from a two-chamber pressurized package. For methods used to test effectiveness, see [153, pp. 447 – 448].

In dry or electric shaving, swelling of the hairs is not desired; hence, for example, high-volume-percent alcohol solutions are applied to

dewater the skin and stiffen the hairs. Isopropyl myristate is a suitable lubricant additive.

Aftershave preparations often contain 40 – 60 vol % alcohol and have pH values between 5 and 7. Lactic or citric acid is used to adjust the pH, and astringent aluminum salts are often added. Skin-care components include polyglycols, ureas, and polyalcohols.

For sample formulations and further information, see [36, pp. 613 – 626], [153, pp. 447 – 449], [165, pp. 381 – 384, 771 – 781], [171, pp. 156 – 189], [172].

9. Testing Methods

The interactions and effects produced by the application of various hair preparations are determined by *half-head testing* on the hair of experimental subjects. Preparation A is applied to one side of the head and preparation B to the other. Specially trained testers, usually hairdressers, then assess which of the two preparations is more effective in producing the desired hair-care effect(s).

Testing criteria include combability, feel, color, luster, manageability during hairstyling, curliness, durability (hold) of waving, setting ability, buildup of product residues, formation of dust on combing, and static charging of dry hair. The testing of hair colorings is described in Section 5.2.5. Long-term tests are used to determine whether the quality of the hair structure is maintained, improves, or deteriorates after repeated use. If the hair has been damaged, it resists styling; has a dull, rough feel; and lacks luster. Naturally, the judgment of the testers is subjective, but it can be rendered more objective by using appropriate statistical methods [173]. Uncertainties in the ranking of a product occur when hair quality changes gradually, climatic conditions vary, and only few numbers of subjects are involved in the tests.

Several of the above criteria can be evaluated reliably by instrumental measurements. These have the advantage that mixed, uniform batches of hair (in the form of tresses) can be used and several hair preparations can thus be compared directly. Testing conditions are defined, and numerical values obtained, which yield statistically significant results more readily than subjective testing. Unfortunately, internationally valid testing standards have not yet been adopted for quantifying the action and efficacy of hair-care products (as has been done for wool in the International Wool Textile Organization, IWTO, standard, (see also → Wool).

Combability testing usually measures the force required to untangle a randomly tangled hair bundle. The result depends strongly on the friction between the hairs and between the hair and the comb. The force can be measured with a "dynamometric comb" [7], a tensile testing apparatus [174], or a combing machine with rotating combs where the ambient conditions are set automatically [175].

Alternatively, the sound produced by combing hair can be recorded and compared against a scale; this method is used in testing shampoos, setting lotions, and waving products [7, p. 314]. All methods give relative values, which depend heavily on the type and preparation of the hair and on how closely test conditions imitate reality.

The *hold of temporarily set curls* after the use of setting lotions or hair spray is tested with the *curl-retention test* [19, p. 465]. In this test a weight is attached to the curled hair and allowed to hang for a predetermined time. The lengths of the hair before and after weighting are then compared. Differences in the setting effect can best be evaluated for well-defined geometries of the hair and roller at all values of atmospheric humidity [176]. Setting "factors" can thus be calculated [177].

The *elasticity and hold of permanent-wave curls* depend highly on the degree to which neutralization restores the hair to its initial chemical state and its physicochemical equilibrium. Hold is impaired by frequent contact with water and by mechanical deformation in brushing. In the curl-retention test for permanent-waves, curls are best weighted over a long period (24 h) at a high relative humidity (90 % R.H.) or in water containing surfactants. A dynamic elasticity test also simulates practical conditions [7, 9]. Chemical testing with 5,5′-dithiobis-2-nitrobenzoic acid (Ellman's reagent) indicates whether additional thiol groups remain on the waved hair [178] and whether the permanent wave was neutralized sufficiently.

Most hair preparations are designed to reduce the static charge of dry hair and impart tactile and visual "body," natural luster, and a smooth

feel. *Static charging* can be produced by repeatedly combing hair strands with a hard-rubber comb [179]. The discharge current measured in a Faraday cage indicates whether the cationic polymers present in most setting lotions, conditioning treatments, and shampoos adhere too tightly to the hair, causing it to acquire a charge.

A compression test on tresses can show how much *body* fine hair gains, for example, after permanent waving or treatment with a hair-care product [180]. The test measures the force required to pull treated hair through a series of increasingly narrow apertures.

Objective measurement of the luster or feel of hair strands is difficult. Very few methods yield any correlation with practical experience. Image analysis represents a new approach to the measurement of reflected light, i.e., luster [7]. More recently, shine measurements in good correlation with consumer assessment have been reported for evaluations that use hair tresses rather than single fibers [181]. The feel of hair may possibly be determined by the Kawabata system, which is used for testing textiles [182].

Study of the *chemical changes* in hair proteins produced by oxidative or reductive treatment is reviewed in [41]. Cysteic acid determinations [183], streaming potential measurements [184], spectroscopic methods,[41] and scanning force microscopy [185] provide information about the condition of the hair surface, whereas strength testing of hair bundles, swelling – sorption measurements, and solubility experiments yield information on the condition of the entire hair sample [19]. Optical methods, such as scanning electron microscopy of the hair surface [186] or the determination of hair birefringence under the optical microscope [187], provide visual evidence of the degree of damage.

10. Toxicology and Legal Aspects

10.1. Toxicology

10.1.1. Introduction

Cosmetic products are used extensively by most humans, at least in the economically developed countries. Many hair cosmetics are used daily or frequently over long periods of time. Consequently, consumer exposure to cosmetic ingredients may be considerable, so that current legislation, which defines far reaching safety requirements for cosmetic products, appears to be justified. Safety requirements from a regulatory point of view and consumer expectations are adequately summarized by the corresponding text within the EU Cosmetics Directive: "A cosmetic product put on the market within the community must not cause damage to human health when applied under normal or reasonably foreseeable conditions of use ..." [188].

The history of cosmetology, past experience with the safety of cosmetic products, and in particular statistics published by intoxication advisory centers show that the cosmetic industry in general has met these criteria [189]. This is achieved by continuously evolving safety assessment strategies which take into account the actual state of the art in safety or toxicity testing.

10.1.2. Strategy for Safety Assessment of Cosmetics

A complete safety assessment of cosmetic products has to cover the aspects microbiology, physicochemical characteristics, and human safety with regard to occupational and consumer exposure. This section exclusively deals with safety with regard to occupational and/or consumer exposure.

Safety assessment of hair preparations is conducted in two highly integrated steps at the ingredient and finished-product levels. In general, the potential of a hair preparation for sensitisation, genotoxicity and all other systemic toxic effects is evaluated on the basis of the ingredients' characteristics. Adequate consideration of human exposure is already of fundamental importance for data interpretation at the ingredient level. Safety assessment for each individual ingredient has to cover the different partial aspects of toxicology, such as acute and subchronic systemic toxicity, local effects, sensitizing potential, mutagenicity, tumorigenicity and teratogenicity [190]. Whether experimental data on all these aspects are necessary depends on the expected external and systemic exposure that will result from use of the hair preparation under consideration. Knowledge about the conditions of

human use enables the safety assessor to investigate and judge the possible route of entry into the human organism, e.g., by percutaneous absorption, oral ingestion or absorption via the respiratory tract. The main source of toxicological data on ingredients are the manufacturers' documents (raw material suppliers). Because these companies generally have to comply with national or supranational legislation on chemicals, they are obliged to generate toxicological data [191]. Additional sources are publications in the scientific literature, monographs released by health authorities or other official bodies, expert judgement based on analogy to chemically related substances, and in-house experience from the marketing of similar products containing the particular ingredient. In almost all cases, only a small range of experimental studies will remain to be done on the finished product. These include skin compatibility studies in humans under relevant test conditions [192]. The question of possible interactions between different ingredients will usually be evaluated on the basis of experience, and only in rare cases will additional experiments be required. Depending on the nature of unresolved problems after completion of this assessment, additional experiments may be initiated, in vitro or, very rarely, on animals or human volunteers.

An adequate safety assessment of hair preparations can not be performed by means of a formalized procedure such as working through different steps on a checklist. Instead, flexibility and expertise cosmetic chemistry and toxicology are necessary. The four main elements of the health related in part of safety assessment are

1) Exposure assessment
2) The toxicological profile of ingredients
3) The test results obtained with the finished product
4) Post-marketing (human) experience with analogous products

For each type of hair preparation key areas which are of major importance during safety assessment can be defined, e.g., the question of inhalative toxicity and respiratory sensitization in the evaluation of aerosol products [193]. In particular, permanent-wave and hair-color preparations usually contain chemicals that are more reactive than the majority of basic cosmetic ingredients. These active ingredients can be expected to interact with biological systems, and thus complete toxicological characterization is an essential part of the early screening phase. In contrast, rinse-off products such as shampoos and conditioners are usually not very challenging for a safety assessor in view of the nature of the ingredients and the conditions of use (exposure). Slight adverse local effects which can be observed in particularly susceptible individuals are mainly caused by surfactants [194].

As regards exposed humans, the safety assessor has to differentiate between the two main user profiles, consumer and professional, whereby the latter may differ in exposure route and duration. Finally the available toxicological or safety data must also be used to assess possible risks of foreseeable excess use, realistically conceivable misuse, and use by consumers suffering from certain diseases.

10.1.3. Test Methods

10.1.3.1. Basic Principles

In contrast to legislation on safety testing of chemical substances such as pesticides or pharmaceuticals, no detailed guidelines on the test programme and individual test methods have been issued for cosmetic ingredients. However, the fact that the toxicological profile of the ingredients has to be considered for safety assessment of cosmetics is clearly stated in the 6th Amendment to the EU Cosmetics Directive [188]. Moreover, a draft guideline prepared by the Scientific Committee on Cosmetology (advisory panel to the European Commission), intended for publication in 1997, clearly defines the range of toxicological aspects to be covered [195]. Because toxicology is a universal science, requirements for cosmetic ingredients do not fundamentally differ from those for chemicals intended for other areas of use. The toxicological profile of a chemical substance or a mixture of chemicals consists of information about [190, 195]:

– Acute systemic toxicity
– Local compatibility or local irritation (ski, mucous membranes, eye)
– Sensitizing potential (allergenicity)
– Mutagenic/genotoxic potential

- Phototoxicity (only under certain conditions)
- Absorption, distribution, metabolism and excretion (toxicokinetics)
- Subchronic and chronic systemic toxicity
- Reproductive and developmental toxicity
- Tumorigenic potential

Depending on the use of a chemical (exposure characteristics), emphasis will be placed on only a few of the above areas. It is, however, not acceptable to disregard completely one or more of these aspects. This does not mean that all questions must be answered by using standardized toxicological test methods. Instead, all scientifically relevant information is valuable, including theoretical considerations, structure – activity relationships, and results from unconventional experiments, provided they are interpreted on the basis of adequate scientific expertise. With regard to international regulatory acceptance of test data, the study protocols should adhere as closely as possible to standardized test guidelines, as published by the OECD [196] or comparable official bodies.

The cosmetics legislation in the European Union (see Section 10.2. Legal Aspects) is putting particular emphasis on the use of non-animal (alternative) test methods for the purpose of toxicological characterization of cosmetic products and cosmetic ingredients. Scientists working in this field should therefore be informed about the progress achieved in development of alternative methods. Depending on the status of scientific and regulatory acceptance of a given alternative method, its use should be carefully and seriously considered.

10.1.3.2. Systemic Toxicity Studies

Systemic toxicity studies determine whether a test compound can damage the individual organs and tissues with respect to structure or function. All possible routes of entry into the organism have to be considered, and these depend on the physicochemical properties of the test compound and the use pattern of the finished product. Apart from the dermal (percutaneous) absorption, ingestion and inhalation must be considered. A basic test usually performed at the beginning of the experimental program is the acute toxicity study. This experiment should enable the intoxication pattern after a single exposure to very high amounts of the test compound to be assessed. Traditionally, the results of such studies are summarized as LD_{50} values (→ Toxicology). The LD_{50} value is used for classification and labeling. The toxicologist, however, makes use of all details of the study results, which include the type and severity of intoxication symptoms, the time of onset and duration of clinical symptoms, and type and severity of organ damage [197 – 199]. Consideration of this complete range of study results allows an improved occupational and consumer risk assessment to be made.

There are various reasons for considering the possible consequences of a repeated, continuous, and long-term exposure of humans to cosmetic ingredients. Hair preparations used for cleansing, conditioning, and styling are usually applied frequently (daily) and for long periods of time. If such products contain biologically reactive ingredients that can penetrate the skin, then the question of systemic toxicity must be further investigated. These conditions are mimicked by subchronic and chronic toxicity studies, in which the test compound is administered in graded dose levels over an adequate period of time to a group of animals [200 – 202] (→ Toxicology). Test compounds that appear unproblematic following extremely high single doses in acute toxicity studies can exert massive biological effects after repeated administration of relatively low dosages. Such profiles are known for natural biologically active substances and synthetic chemicals such as pharmaceuticals. In addition, the possibility of accumulation in the body might lead to toxic effects even after minimal exposure over long periods of time. Thus, subchronic and chronic toxicity studies provide information about the threshold of exposure beyond which the induction of toxic effects must be expected, the target organs of toxicity, and the nature of adverse health effects. The results are used to decide whether the estimated exposure of humans to the tested ingredient resulting from use of a given hair preparation is safe.

Replacement of these rabbit primary irritation test methods by non-animal alternatives has been the top priority for the expert scientists in the cosmetic industry. Although there is still no validated and officially recognized stand-alone method available, experienced toxicologists can make use of a large variety of different in vitro

tools for assessment of local irritation of chemicals and mixtures of chemicals. Whereas artificial skin models seem to be the most promising approach for skin compatibility testing, ex vivo assays such as the bovine corneal opacity test, the chicken enucleated eye test, the isolated rabbit eye test or the hens egg test on the Chorio-Allantois membrane are currently considered to give the most reliable results. Such tools can be particularly useful for comparative testing of chemicals or complex preparations in case that there is already broad experience with irritation data from structurally related chemicals or similar preparations. An adequate use of these in vitro methods does definitely require a large in-house database and specific experimental expertise and cannot be recommended as a standard approach.

10.1.3.3. Local Compatibility

Local compatibility studies (also known as local irritation studies) assess whether a test compound can induce damage directly at the sites of contact with the human body. For hair preparations these are mainly the skin, eyes, and in certain cases also the upper respiratory tract mucosa. Local compatibility results obtained with undiluted compounds are of limited relevance to the prediction of local compatibility of finished hair preparations. Therefore, dermatological testing of final formulations is indispensable. Studies with undiluted compounds are nevertheless helpful in selecting of suitable ingredients during the early phase of product development. For ingredients known to be strong irritants as pure compounds, the irritation threshold should also be determined experimentally.

Workplace related dermatoses are among the most frequent occupational diseases in industrialized countries. The prevalence of dermatoses is also increasing in the general population, an observation which is associated by many experts with the increased exposure to a growing number of chemicals. Of the available experimental methods, the dermal compatibility study in the rabbit (primary irritation, skin) is the test method with the broadest scientific and regulatory acceptance [203]. The rabbit is considered particularly sensitive towards chemically induced skin irritation.

Depending on the type of hair preparation, contact with mucous membranes (predominantly the eye) is either unavoidable or must be expected from inadvertent contamination. The classical test method for evaluating the consequences of such contact is the (primary) eye irritation study in the rabbit (Draize Test, → Toxicology, Chap. 4.4) [204]. Again, this test model is known to be particularly sensitive towards chemical injury and offers additional tissues such as the cornea and iris as objects of examination apart from the conjunctiva (mucous membrane) [205]. The determination of the concentration – response relationship for local effects is of essential importance because all cosmetic ingredients are used in the form of a complex formulation composed of different substances.

10.1.3.4. Sensitizing (Contact-Allergenic) Potential

Allergy is a disease characterized by a massive (over)reaction of the organism to the contact with a chemical. Usually, the allergenic response occurs only after a repeated contact. The process which changes the reaction of the organism from normal to hypersensitive is termed sensitization. There are vast differences in potency of sensitizing effects between different chemicals, as is true for the individual susceptibility of humans towards the sensitizing effects of a given chemical. Therefore, the allergenic effects of a chemical usually affect only few individuals from a given large group of humans. The severity of the allergenic reaction is not linearly correlated with the dose of the allergen. Often only traces of a chemical are sufficient to induce an allergic reaction [206].

Cosmetic ingredients (and chemicals in general) cannot simply be categorized as sensitizers or nonsensitizers. In principle, the statement is justified that for any chemical at least one human could be found who develops an allergy. Animal studies are used to differentiate between cosmetic ingredients without relevant sensitizing potential and those whose sensitizing potential warrants a warning text on the label or use restrictions. Cosmetic ingredients are usually tested on the guinea pig to assess their sensitizing potential following dermal contact (→

Toxicology, Chap. 4.5). The guinea pig is the test species of choice for this type of experiment because it is highly susceptible towards the allergenic effects of chemicals. The Magnuson – Kligman maximization test is one of the most reliable methods of the various test protocols. The maximization test is able to also identify chemicals which are regarded as weak human sensitizers. In contrast, the Bühler test has a lower sensitivity but is increasingly used for characterizing cosmetic ingredients. It uses exclusively dermal administration of the test compound, which mimics the use conditions of cosmetic products better than the intradermal injection of the maximization test [207].

In the 1990s, the local lymph node assay (LLNA) in the mouse has been qualified as a stand-alone alternative to the guinea pig tests. Following rigorous validation efforts, the LLNA has ultimately found broad scientific and regulatory acceptance as a test method providing both, improvements in scientific value and animal welfare (lower number of animals; less suffering). The scientific basis for the LLNA is the measurement of the incorporation of ^{3}H-methyl thymidine into lymphocytes in draining lymph nodes of mice topically exposed to the test substance. The endpoint of interest is a stimulation index giving the ratio of thymidine incorporation in lymph nodes from dosed animals compared to control animals. The test is considered to indicate a relevant sensitizing potential when the stimulation index exceeds 3 ($SI > 3$). In contrast to the classical guinea pig tests, the LLNA results are providing a direct measurement of sensitizing potency of the tested chemical.

Research on a number of in vitro approaches for assessment of the sensitizing potential is currently being conducted. So far, the most advanced methods under consideration have reached the prevalidation stage and thus are not sufficiently mature for stand-alone use in human safety assessment.

10.1.3.5. Mutagenic/Genotoxic Potential

Mutations are alterations of the genetic information inside living cells which occur spontaneously or are induced by radiation, chemicals or viruses. Depending on the type and severity of alterations in the genetic material three types of mutations are distinguished: gene, chromosome, and genome mutations [208, 209].

Gene mutations (point mutations) are molecular changes of DNA not extending beyond one gene and therefore not affecting the microscopic aspect of the chromosomes. Chromosome mutations are microscopically detectable structural changes to chromosomes. The term genome mutations is used for mutagenic effects which induce numerical changes in the genome, such as missing or supernumerary single chromosomes or doubled, tripled, or multiplied sets of chromosomes.

Mutations may affect the genetic information of gonadal cells within the testes or ovaries or that of somatic cells (cells of any other tissue or organ of the body). Mutations in gonadal cells may lead to impaired fertility, to embryonic or perinatal death. Nonlethal gonadal mutations usually lead to inherited and heritable (genetically fixed) diseases. Although the consequences of somatic mutations are limited to a small part of the entire organism, their occurrence deserves particular attention because they are associated with the development of tumors and ageing phenomena. The currently discussed model of tumor development assumes definitely that mutations in somatic cells contribute fundamentally to the process of tumorigenicity in mammals [210].

The following test systems are superior in terms of practicability, standardization and validation and are therefore preferentially used for mutagenicity testing of all types of chemicals. They are all in vivo and in vitro tests in somatic cells. Test methods for the detection of mutations in gonadal cells are scientifically and technically demanding, time consuming, and expensive and are therefore mainly used in special cases.

The Salmonella microsome mutagenicity test, also known as Ames Test (→ Toxicology, Chap. 4.9.1.1) is the most widely used mutagenicity assay [211].

The Ames test is suitable for the detection of point mutagenic effects of chemicals with relatively low expense in terms of time and resources. However, a positive result only means that the test compound is a mutagen in bacteria under test conditions. This also holds true for other in vitro test systems, so that a positive result will lead to further investigations.

For the detection of gene mutations in vitro in mammalian cells cell lines originating from the Chinese hamster or the mouse are generally used (→ Toxicology, Chap. 4.9.2.2) [212]. In addition to a number of in vitro assays [213], the mouse micronucleus test (→ Toxicology, Chap. 4.9.5.3) is routinely used for the indirect detection of a clastogenic (chromosome-breaking) effect. The micronucleus test is also suitable for the detection of spindle poisons, which can cause genome mutations. The micronucleus test is widely accepted as a rapid in vivo mutagenicity test [214].

In human risk assessment, the extrapolation of the results from a complete mutagenicity test battery is problematic. If there is convincing evidence from the test results that the test compound had no mutagenic effects, it can be concluded that the probability of a mutagenic risk in humans is acceptably low. If the results clearly indicate interaction of the test compound with genetic mechanisms, they must be interpreted as evidence for an increased genotoxic and tumorigenic risk in humans. Animal studies that allow quantitative assessment of human genotoxic risk are expensive and require large numbers of animals. Their use is therefore only justified under particular circumstances, e.g., in the case of chemicals for which no suitable alternatives are available.

10.1.3.6. Reproductive Toxicology

Reproductive toxicology deals with possible effects of chemicals on reproduction, which can be manifested as impairment of fertility or of the development of the progeny. These studies are not mandatory for all cosmetic ingredients and are conducted only if a relevant systemic exposure is expected. Reasons for increased concern in terms of reproductive toxicology include:

- Structural similarity with known embryotoxic or fertility impairing compounds
- Indications of a very high biological/toxicological activity from other studies
- Extensive exposure, extended contact time and/or high percutaneous absorption rates

Throughout the course of the reproductive cycle there are many different targets for the adverse effects of chemicals. Considering the life span of one generation, these targets could be maturation of sperm or ova female sexual cycle, fertilization, implantation, prenatal development, delivery, and early postnatal development of the offspring. Reproductive toxicology is investigated with the aid of animal experiments. The rat is the predominantly used species, but mice and rabbits are also frequently employed in this type of experiment [215].

Comprehensive characterization of the reproductive toxicological potential of a test compound can be achieved by conducting multigeneration studies (→ Toxicology, Chap. 4.7.4) [216].

Embryotoxicity studies assess impairment of prenatal development. For this purpose pregnant female animals (usually rats) are dosed with a test compound throughout the most sensitive phase of prenatal development [217 – 219] (→ Toxicology, Chap. 4.7.2).

All subsequent phases of the reproductive cycle are covered by peri- and postnatal studies (→ Toxicology).

Developmental and reproductive effects are regarded as threshold phenomena. Therefore, human risk assessment is performed by comparing the expected exposure to the compound with the maximum dose tested in the various animal experiments that did not induce adverse effects (no observed effect level, NOEL). If there is a relevant risk of reproductive or developmental effects under human use conditions, then the test compound is not suitable as a cosmetic ingredient because contra-indications or use restrictions are not practicable for hair-care products.

10.1.3.7. Tumorigenic Potential

Chemicals which induce or enhance the growth of tumors are termed tumorigens or carcinogens. Although only malignant tumors are called cancer, the term cancerogenicity is often used as a synonym for the correct term tumorigenicity.

For evaluation of the tumorigenic potential of a cosmetic ingredient, the complete range of toxicological information is considered. The results of mutagenicity studies are of particular importance because positive results from such experiments are also indications of a tumorigenic potential. This suspicion might be further supported by results from subchronic or chronic

systemic toxicity studies (e.g., proliferation of growth of certain tissues) or by structural analogy to known tumorigenic compounds. If there is some evidence of tumorigenicity at this stage, special tumorigenicity studies in animals might be considered. Because these studies are very time consuming, expensive, and require large numbers of animals, they will only be conducted on very important ingredients for which no alternatives are available. The animal experiments for detection of a tumorigenic potential are usually performed in rats and/or mice and include the continuous daily administration of the test compound over a substantial part of the life span of the test animals, which is usually set at two years for laboratory rodents. In addition to the continuously performed in-life observations, which include palpation to detect tumors at the earliest possible time, a comprehensive program of macroscopic and histopathological (microscopic) examinations for the post-mortem evaluation of organs and tissues is an essential part of standard tumorigenicity studies [220].

For tumorigenic risk assessment, human experience is of particular importance in addition to experimental data. Depending on the quality of such epidemiological data, problematic results from animal toxicity studies might even be outweighed. There is general agreement among cosmetic toxicologists from industry and public health agencies that chemicals with a relevant tumorigenic potential are not suitable as cosmetic ingredients.

10.1.3.8. Toxicokinetics

Toxicokinetics describes the time curve of a chemical's concentration within different compartments of the organism. Toxicokinetics includes all processes which determine the fate of a chemical in a living organism, such as absorption, distribution, biotransformation (metabolism), and excretion.

For hair preparations the most important toxicokinetic information concerns the question of percutaneous absorption. Information about this parameter enables the externally applied amount of a hair preparation (dermal dose) to be transformed into a value representing the systemically available amount of a given ingredient of this preparation (internal dose). The internal dose is the relevant basis for all risk related considerations of systemic toxicity. Percutaneous absorption of ingredients is investigated with the aid of in vitro tests [221, 222]. The most widely accepted method utilizes skin from pigs, rats, or even humans. The skin membranes are mounted on cylindrical chambers with a cross-sectional area of ca. 10 cm^2. The test formulation is applied to the outer surface of the skin membrane, and the portion of the test compound that penetrates is collected in a receptor fluid contacting the inner surface. Provided that the application conditions (type of formulation, concentration of the test compound, and area of dose, and exposure time) mimic the human use situation adequately, the results of such in vitro experiments give a reliable estimate of the absorbed portion which has to be expected for human use of the hair preparation. Whereas the penetration rates through rat skin usually overestimate absorption through human skin, the results obtained with pig skin and human skin in vitro predict reliably the human in vivo situation [221 – 223].

For spray products which deliver inhalable aerosols, inhalative exposure must be considered additionally. This parameter can be determined by animal experiments, e.g., inhalative toxicity studies (→ Toxicology, Chap. 4.2.3) [224]. However, if the physical characteristics of the aerosol, in particular the concentration of toxicologically relevant chemicals and particle or droplet size distribution are well-known, then a theoretical estimation of the systemic exposure can give reliable values because a very large portion of the inhaled material is usually absorbed in the alveolar parts of the lung due to the large contact area.

10.1.4. Description of the Safety Assessment Process

In principle, safety assessment already starts with the first steps of product development. The cosmetic chemist selects the ingredients from a pool of chemicals generally suitable for the intended cosmetic use. In this respect, suitability means for example that the ingredients are compatible with the cosmetics legislation in the countries intended for marketing (positive/negative lists appended to the EU cosmetics directive) and are nonmutagenic and non-

tumorigenic. Product innovations are often be achieved by introducing new chemicals which must be characterized toxicologically according to the principles described in Section 10.1.3.

In the succeeding phase, the safety assessor considers human exposure. Apart from the exact qualitative and quantitative composition of the product, detailed knowledge of the anticipated human use conditions is required, such as the amount used per application, frequency of use, contact time with the skin (rinse-off or nonrinse product), the size of the contact area, possible routes of exposure (dermal, oral, inhalation), the probability of eye contamination (viscosity of the preparation) and the target consumer group (males, females, children). In addition, special consideration will be given to the exposure assessment for professional users of hair preparations in salons.

The information about toxicological profiles of ingredients and exposure scenario are integrated to reveal possible areas of concern. In principle, the contribution of each individual ingredient to local and systemic tolerance will be considered. Many routinely used cosmetic ingredients can induce dermal irritation if applied undiluted. Because chemical skin irritation is a concentration-dependent phenomenon, an irritation threshold can be defined. Comparison of the irritation threshold with the use concentration may already adequately answer the safety question. However, the issue is complicated by the fact that many cosmetic ingredients interact with each other resulting in increased or decreased skin irritation. Final evaluation therefore requires adequate experience with products of similar composition or experimental results obtained with mixtures of ingredients. The risk of contact allergenic effects is initially judged by considering the sensitizing potential of each individual ingredient at its concentration in the formulation. If the available experimental data and human experience appear to be irrelevant because exposure conditions differed from those anticipated for the product under review, then additional investigations are required.

Interactions among ingredients which enhance or reduce dermal penetration could also influence the sensitizing potential. Likewise, the percutaneously absorbed amount of each individual ingredient is required to assess possible systemic (toxic) effects. The integration of information about external exposure (dermal dose), corrected by an absorption factor to yield the internal or systemic exposure, possible influences of other components of the preparation and the toxicological profile of the ingredients as observed in animal studies including threshold values (NOELs), dose – response curves, and target organs of toxicity, are usually included in the calculation of a safety factor. The arithmetic procedure which leads to a safety factor or safety margin is common to toxicological risk assessments for all types of chemicals. The basic principle underlying following formula has also been recommended by the Scientific Committee on Cosmetology [195] for quantitative risk assessment with regard to systemic effects of cosmetic ingredients (e.g., applicable for hair preparations of the nonaerosol type):

$$D_{ext} \cdot C_{ingr} \cdot A_{syst} \cdot F_{CT} \cdot \frac{1}{60\text{kg} \cdot \text{NOEL}} = \text{safety margin}$$

D_{ext} total amount used per day (mg) in the case of hair preparations corrected by the "distribution factor scalp/hair" of 0.1

C_{ingr} concentration of the particular ingredient in the hair preparation

A_{syst} absorption factor (dermal)

F_{CT} correction factor for short contact time (e.g., 0.1 for rinse-off products)

NOEL highest dose tested in subchronic or chronic systemic toxicity studies or in reproduction toxicity studies without any indication of adverse effects

For the protection of consumers from "classical" systemic toxic effects such as organ toxicity and impairment of physiological functions (cardiovascular system, kidneys, intestinal tract) or the endocrine system, a safety factor of 100 is usually considered to be the minimum requirement. Depending on the nature of toxic effects observed in animal experiments beyond the NOEL, larger or smaller safety margins might be necessary or acceptable. Regulators have to act in a conservative manner and therefore they tend to request safety margins beyond 100 if the first toxicological manifestations concern prenatal development (embryotoxicity), the nervous system, or the immune system.

In addition, possible chemical reactions such as neutralization, hydrolytic cleavage, complex formation, and others, which could be expected

due to the reactivity of the ingredients must be carefully evaluated with regard to their secondary biological consequences. For the majority of newly developed hair preparations, possible interactions among ingredients can be predicted theoretically and from experience with analogous mixtures of compounds and products. However, additional experiments must be conducted in those cases where information gaps are left. Commonly, the predicted safety of new hair preparations is confirmed by appropriate tests on human skin, and pre-market controlled studies for other purposes such as product performance can also yield valuable safety information.

The question of consumer safety is not only a function of product composition but depends in addition on the use conditions. Thus, the use instructions must be taken into account by the safety assessor and in certain cases they may have to be supplemented by special warning texts such as "avoid contamination of the eye because the product might cause irritation".

Following the integration of available human experience as the last step in the safety assessment process, the final safety clearance will enable the progress of the new hair preparation to the marketplace.

10.2. Legal Aspects

10.2.1. General

10.2.1.1. Legal Aspects in the European Union

In the European Union (EU) hair preparations are classified as cosmetics and subject to legal provisions stated in the EC Cosmetics Directive 76/768/EEC [225]. (The implementation of the Directive into national cosmetic regulations by each member state is being updated continuously.) In principle, the responsibility for cosmetic products lies with the manufacturer. Postmarket surveys as well as occasional inspections at the manufacturers' facilities by the competent authorities — instead of premarket product registration — ensure that the products comply with the relevant regulations. As a basic requirement cosmetics ". . . must not cause damage to human health when applied under normal or reasonably foreseeable conditions of use . . ." (Article 2 of the EC Cosmetics Directive). A safety assessment by a qualified person must be available for each finished product.

For cosmetic colorants, preservatives and UV filters no substances other than those listed in Annexes IV, VI, and VII of the Directive may be used. Any new substance with one of these functions has to be registered with the Scientific Committee Cosmetology of the European Commission before being used in cosmetics. Other ingredients which are neither banned (Annex II) nor restricted (Annex III) may be used without limitations provided Article 2 is followed.

Each cosmetic product introduced to the EU market has to be provided with an ingredients label that uses the common names listed in the respective EU inventory [226] based on the International Nomenclature of Cosmetic Ingredients (INCI). New raw materials are subject to the requirements of the Dangerous Substances Directive [227] in addition to the Cosmetics Directive.

Some EU member states, however, depart from the EC Cosmetics Directive regarding restrictions on certain raw materials (Denmark [228], Italy [229]), and labeling requirements (France [230]). These deviations from the EC Cosmetics Directive complicate free trade within the EU. France [231], Germany [232, 233], and Spain [234] require notification to the poison information centers before a product is marketed. A common system based on framework formulations is foreseen for all EU member states.

10.2.1.2. Legal Aspects in Other Countries

In the *United States*, certain cosmetics are classified as over-the-counter (OTC) drugs (i.e., for sale without prescription) and are subject to registration [235]. The list of cosmetic color additives is strictly limited, and each production batch has to be certified by FDA. In preparations sold directly to the consumer all ingredients have to be listed on the label [236].

In *Japan*, cosmetics are classified as quasi-drugs or cosmetics. New raw materials have to be registered and extensive toxicological data submitted. All raw materials have to comply with official standard specifications [237 – 245]. Human patch tests from other countries are recog-

nized only if data are obtained from Asian test persons. Until 1986, all preparations had to be registered. Since then, Comprehensive Licensing Standards by Category (CLS) have gradually been introduced for cosmetics [246]. Notification to the health authorities is sufficient for products that comply with the CLS. Other cosmetics and all quasi-drugs have to be registered with the health authorities. As announced by the Japanese Ministry of Health and Welfare in spring 1997, a deregulation of the Pharmaceutical Law is planned to simplify the procedures for cosmetics in the near future.

The cosmetic regulations of *other countries* are often influenced by those of the United States or the EU. For example, provisions in Norway [247] and Turkey [248] are closely modeled on the EC Cosmetics Directive. The countries of Central and Eastern Europe are in the process of harmonizing their cosmetic regulations with the EC Cosmetics Directive. Premarket product registration is required for cosmetics in Turkey, most countries of Central and Eastern Europe, Latin America, and Southeast Asia.

10.2.2. Individual Hair Preparations

Shampoos The general provisions stated in Section 10.2.1 apply in the EU countries. Not all substances allowed in the EU may be used in other countries; provisions in specific countries must be complied with. Antidandruff shampoos are classified as OTC drugs in the United States [249] and as quasi-drugs in Japan [239, 242].

Hair-Bleaching Preparations In the *EU*, peroxosulfates can be used without restrictions. Some countries (e.g., *Thailand* [250]) limit their concentration. The *United States* does not have any specific regulations. In *Japan*, hair-bleaching preparations are classified as hair dyes of quasi-drugs [242, 251].

Hair Dyes

European Union. The substances *o*-phenylenediamine, 4-methyl-*m*-phenylenediamine, 1-methoxy-2,4-diaminobenzene, 1-methoxy-2,5-diaminobenzene, 2-amino-4-nitrophenol, 2-amino-5-nitrophenol, 4-ethoxy-*m*-phenylenediamine, catechol, pyrogallol, 4-amino-2-nitrophenol and 2-methyl-*m*-phenylenediamine are banned in the EU (EC Cosmetics Directive , Annex II) [225].

Other phenylenediamines and methylphenylenediamines, *N*-substituted derivatives of phenylenediamines and methylphenylenediamines, diaminophenols, hydroquinone, α-naphthol and resorcinol are permitted, with restrictions on concentration. Except for α-naphthol, these substances may be employed for dyeing eyelashes and eyebrows by professionals only. Warning labels are also prescribed (EC Cosmetics Directive, Annex III, Part 1) [225]. Other appropriate substances may be used as long as they are neither banned (Annex II) nor restricted (Annex III) and the finished product complies with Article 2 of the EC Cosmetics Directive [225]. In addition to the EU provisions, 2-nitro-*p*-phenylenediamine and 4-nitro-*o*-phenylenediamine are banned in Italy [229], and 2-nitro-*p*-phenylenediamine, 4-nitro-*o*-phenylenediamine and *m*-phenylenediamine in Denmark [228].

United States. The United States requires a special warning label. With this label, any hair dye can be used without restriction [252].

Japan. In Japan oxidation hair dyes are classified as quasi-drugs [242]. A list of permissible hair dyes has been issued [251]. New dyes have to be registered with the Ministry of Health and Welfare (MHW) before being used in products [239].

Permanent Wave, Hair-Straightening and Hair-Removal Preparations. The *EC Cosmetics Directive*, Annex III, Part 1, restricts the pH range of permanent wave preparations and hair straighteners based on thioglycolic acid, its salts, and esters (pH 7 – 9.5 for the acid and salts, 6 – 9.5 for esters). The maximum concentration (calculated as thioglycolic acid) is 8 wt % for general use and 11 wt % for professional use. A special warning label is required. Hair-removal preparations are also subject to restrictions and require special warning labels; thioglycolate esters are not, however, allowed [225].

In the *United States* no legal restrictions exist. However, the Cosmetic Ingredient Review (CIR) Expert Panel considers 15.4 wt % max. of thioglycolic acid as safe in permanent-wave products [253]. The CIR recommendation is respected by the manufacturers of permanent waves. The FDA recommendations for hair straighteners are given in [254].

In *Japan*, permanent wave products are classified as quasi-drugs [242]. Thioglycolic acid and its salts are permitted, as is cysteine. Restrictions on concentration and pH must be taken into account. Thioglycolate esters are not allowed. Concentration limits also apply to neutralizers [255].

Aerosols. Here the term aerosol refers to hair cosmetics filled in pressurized containers, such as hair sprays. The use of chlorofluorocarbons is banned in all countries that are following the Montreal protocol on the protection of the ozone layer in any kind of hair preparations.

In the *EU*, methylene chloride is permitted as a solvent up to a concentration of 35 wt %. (EC Cosmetics Directive, Annex III, Part 1) [225]. Special warning labels are required by Commission Directive 94/1/EC [256]. In *Austria*, pressurized containers with > 45 wt % or > 250 g of flammable ingredients require specific storage conditions [257]. General requirements for aerosols in the *United States* are given in [258]. Based on the Federal Clean Air Act the content of volatile organic compounds (VOC) is restricted in several states, such as California, New York, etc. [259]. In *Japan* the internal pressure of aerosols is restricted to 8 kg/cm^2 at 30 °C. [260]. For specific labeling requirements, see [261].

Other Hair Care Products. In the EU, some preservatives may be added in high concentration provided they do not act as preservatives but have another function (e.g., conditioning or antidandruff agent) which must be apparent from the presentation of the preparation (EC Cosmetics Directive, Annex VI, Preamble) [225]. When products containing alcohol (ethanol) are exported, the alcohol-denaturation provisions of the country of destination have to be followed. In the United States antidandruff preparations are regarded as OTC drugs [249]. Specific restrictions on volatile organic compounds (VOC) for certain product groups are stated in [259]. In Japan all antidandruff preparations are classified as quasi-drugs [239, 242].

1. Introduction

Hard materials are solid substances with high intrinsic hardness values: between 8 and 10 on the Mohs' scale, but occasionally lower. The hardest of all known substances is diamond (→Carbon, Chap. 2.) with a Mohs' hardness of 10 (ca. 10 000 on the Vickers scale) [1].

The technology of hard materials forms a part of materials science and technology that can be called "hard materiology." The manufacture and use of these special substances involves the sciences of chemistry, physics, metallurgy, and powder metallurgy (sintered metals).

The classification of hard materials may be based on their occurrence and manufacture, or on their properties and uses. Their commercial importance is their use in the cemented carbide and abrasives industries (→Abrasives) and as wear-resistant materials (tribology).

Hard materials occur naturally or may be synthetic. In nature they usually are found as elements or oxides, some of them precious stones such as diamonds, rubies, or sapphires. The classification of natural and synthetic hard materials is summarized in Figure 1.

Metallic and nonmetallic hard materials may be defined according to their properties and uses. Of the metallic materials, the most commonly used are the hard metals. Physical properties, such as electrical and thermal conductivity, luster, and color, are taken into account. This classification depends on the bond character, which can vary from metallic or covalent to ionic (heteropolar), corresponding to the metallic and nonmetallic hard materials (Table 1) [2].

Table 1. Classification of synthetic hard materials

Metallic	Nonmetallic
Binary compounds	Oxide ceramics
Carbides∗	Aluminum oxide (Al_2O_3)
Nitrides∗	Chromium oxide (Cr_2O_3)
Borides∗	Titanium oxide (TiO_2)
Silicides∗	Zirconium oxide (ZrO_2)
Multicomponent systems	Other oxides
Mixed carbides	Mixed oxides
Mixed nitrides	
Mixed borides	Nonoxide ceramics
Mixed silicides	Carbides (B_4C, SiC)
Carbonitrides	Nitrides (AlN, CBN, Si_3N_4)
Boronitrides	Borides (α-AlB_{12}, SiB_6)
Borocarbides	
Silicoborides	Elements
Silicocarbides	Boron
Siliconitrides	Carbon
Double carbides, complex carbides	Silicon
Intermetallic compounds (Laves phases)	Cermets (composites)
Mixed hard materials without binder	Nonmetallic hard material and metal
Hard material alloys that can be hardened	

∗ of the refractory metals of groups 4 – 6 of the periodic table: Ti; Zr, Hf; V, Nb, Ta; Cr, Mo, W.

Metallic Hard Materials. The most important metallic hard materials are the binary compounds of the refractory metals (transition metals) of groups 4 (titanium, zirconium, hafnium), 5 (vanadium, niobium, tantalum), and 6 (chromium, molybdenum, tungsten) of the pe-

Figure 1. Classification of natural and synthetic hard materials

riodic table with carbon (carbides, →Carbides), nitrogen (nitrides [3], see →Nitrides), boron (borides), and silicon (silicides). The metallic hard materials also include multicomponent systems, double carbids, complex carbides, intermetallic compounds (Laves phases), and mixed hard materials without binder metals.

Hard material alloys that can be hardened consist of titanium carbide bonded in a matrix of hardenable steel (Ferrotitanite). The titanium carbide content can be as high as 50 %, the remainder being mostly iron, with small amounts of other alloying components and, in some cases, other hard materials.

When a metallic hard material is combined with a metal, usually of the iron group, the result is either a *cemented carbide* (hard metal) [4], [5] or a *hard alloy* [6], [7] depending on the ratio of hard material to metal (Fig. 2).

The raw materials for cemented carbides are manufactured on a large scale and include: tungsten, titanium, tantalum, and niobium carbides; tungsten – titanium and tantalum – niobium carbides of various proportions; and recently titanium nitride and titanium carbonitrides, also of various proportions (→Carbides). Cemented carbides are made by powder metallurgy (sintering) and consist of a matrix of hard material (usually tungsten carbide) with a small proportion of metal (usually cobalt). Hard alloys are multicomponent (usually ternary or quaternary) alloys that are made by melting techniques, usually atomization. They generally have an intercalated structure comprising a metallic matrix (usually iron, cobalt, or nickel) with an appropriate proportion of hard materials (carbides, borides, or silicides) for wear resistance.

Nonmetallic Hard Materials. The nonmetallic hard materials include:

1) The oxide ceramics, such as the oxides of aluminum, chromium, titanium, and zirconium, as well as their mixtures (e.g., of aluminum oxide and titanium dioxide) and compounds (e.g., aluminum oxide – magnesium oxide).
2) The nonmetallic carbides, nitrides, and borides, as well as the now very important nonoxide ceramics silicon carbide and silicon nitride (→Ceramics, General Survey, Chap. 1.2.1.).
3) The nonmetallic elements boron, carbon, and silicon.

Cermets (CERamic + METal) (→Ceramics, Ceramic – Metal Systems, Chap. 6.1.), are composite systems consisting of nonmetallic (usually oxide ceramic) hard materials in a metal matrix; they are normally manufactured by powder metallurgy.

Figure 2. Hard material – metal systems

2. Cemented Carbides [8–16]

Cemented carbides or "hard metals" are materials that combine great hardness with metallic properties. They differ from the nonmetallic hard materials in possessing a metallic luster and good electrical and thermal conductivity. They consist of particles of brittle metallic hard materials (usually carbides) in a matrix of ductile binder metals belonging to the iron group (iron, nickel, and cobalt).

The cementation of an extremely hard component with a binder metal of great ductility is a composite material referred to as a cemented carbide. The hard material and the binder metal occur as separate phases. In the typical cemented carbide structure shown in Figure 3, the dark angular grains are the hard material tungsten carbide (WC), which are bound together by thin, lighter colored layers of cobalt. Increasing the hard material content gives a harder product, whereas increasing the binder metal content gives increased toughness.

Figure 3. Microstructure of WC – 9 % Co cemented carbide

History. The manufacture of cemented carbides was made possible by the invention of the electric furnace at the turn of the century. Moissan [17] used this furnace in his attempt to make diamonds. He obtained extremely hard crystals, but analysis revealed that these were metallic carbides and not diamonds. They were not as hard as diamonds but harder than any other known substance. Many attempts were

made to exploit these hard carbides to make tools and wear-resistant components. In 1914, VOIGTLÄNDER and LOHMANN succeeded in pulverizing, pressing, and sintering tungsten carbide to produce wear-resistant articles such as wire-drawing dies [18]. The toughness of these articles was improved by alloying with metals of the iron group. Hot pressing was also successfully employed in addition to melting and sintering techniques.

The decisive step in the development of sintered carbides was taken in 1923 by K. SCHRÖTER and F. SKAUPY of the Osram Study Association [19]. They combined tungsten carbide powder with cobalt powder, formed this mixture into shapes with a press, and heated the shapes above the melting point of cobalt. The tungsten carbide partially dissolved in the cobalt to give a molten eutectic that wetted the tungsten carbide grains. Shrinkage then took place, giving a very dense product. Because their strength values were greater than those of pure carbides, sintered carbides were subsequently used for metal cutting. SCHRÖTER's patents were acquired by the Krupp organization, which in 1925 introduced the first lathes fitted with cutting tools of tungsten carbide–cobalt under the name "Widia" (from the German "*wie Diamant*," i.e., diamond-like). Cast alloys could now be machined at two or three times the speeds achievable with the usual high-speed steel tools. Results on steel were, however, disappointing because of the occurrence of crater wear in the tool material when it was used for turning steel. Diffusion between the hot turnings and the tool caused this deterioration of the cemented carbide.

The vacuum sintering process and the use of titanium carbide (TiC) subsequently allowed great increases in steel-cutting speeds [20].

A tungsten-free cemented carbide (87 % TaC and 13 % Ni) was marketed under the name " Ramet" by Fansteel in the United States. General Electric, in cooperation with Krupp, developed tungsten carbide–cobalt alloys with the trade name " Carboloy." In the mid 1930s ternary cemented carbides (WC, TiC, and TaC) were also produced in the United States [21]. Kennametal also started to manufacture cemented carbides during this period.

In the mid 1970s low-tungsten cemented carbide tools were developed with a fine-grained structure obtained by spinodal decomposition of the components in the system TiCN – MoW – Ni [22]. During the same period WC – Co cemented carbide tools with a grain diamter <1 µm were also produced. These submicron cemented carbide tools combine improved abrasion resistance with satisfactory toughness [23], [24].

Around one fifth of the WC – Co cemented carbides tools produced currently are used in the mining industry. Sweden is an important producer; Sandvik started production there during World War II.

Products containing little or no tungsten carbide have also become important for fine cutting. These are of the type Ti(C, N) with additions of Cr, Mo, W, Fe, Co, and Ni. Much of the initiative in the development and marketing of these materials has come from Japan.

The coating of materials with layers of hard material by means of chemical vapor deposition (CVD) was first described in 1953 [25], [26]. However, this technique was first put to practical use in the mid 1960s for the machining of steel and iron castings [27]. Multilayer coatings (TiC, TiN, and Al_2O_3) were developed in the early 1970s [28], [29].

2.1. Production

Cemented carbides are usually produced by powder metallurgy rather than on melting and casting (→Powder Metallurgy and Sintered Materials). The structure shown in Figure 3 is most often achieved by a sintering technique in which pressed shapes made from the mixed hard material and binder are heated to temperatures well below the melting point of the hard material, but close to the melting point of the binder. The molten binder wets the particles of hard material and results in densification. A short description of the technology of hard metal fabrication can be found in [30–32].

2.1.1. Raw Materials

With the exception of Ti and C, the elements found in cemented carbides rarely occur in the earth's crust. Furthermore, the manufacturing procedure is complex and a high degree of purity is required, so that the overall raw material cost is very high.

Tungsten Carbide (WC) (→Carbides, Chap. 2.1.). Tungsten carbide [*12070-2-1*] can be made from blue tungsten oxide (W_2O_5), ammonium paratungstate (APT) or tungstic acid (H_2WO_4), which are reduced with hydrogen at 800 – 1100 °C to tungsten powder. The particle size of this product is primarily determined by the temperature and moisture content of the hydrogen. Depending on the type of cemented carbide required, particle size can be between 0.3 and 12 µm. Carburization leaves the particle size and size distribution of the tungsten powder largely unchanged. The powder is first intensively mixed with very pure carbon black or graphite. The mixture is then heated to 1500 – 2000 °C. Next the resulting solid cakes of carbide are broken down to a particle size <0.5 mm by means of jaw crushers, hammer mills, blower – beater mills, pin mills, vibratory mills, or ball mills. Vibratory sieves are used to obtain a product of the desired particle size range.

Titanium Carbide (TiC) (→Carbides, Chap. 2.2.). Titanium carbide [*12070-08-5*] is usually obtained from TiO_2 produced by the pigment industry. Carburization with carbon black is carried out at 2100 – 2300 °C, and the product is powdered as described for tungsten carbide. Titanium carbide is mainly used to reduce crater wear resistance of cemented carbides.

Tantalum – Niobium Carbides (→Carbides, Chap. 3.2.). Either an expensive grade of tantalum carbide with a maximum of 1 % niobium carbide is used, or a cheaper grade with a higher niobium content (Ta : Nb = 6 : 1 to 1 : 1). The most common raw material for the manufacture of tantalum – niobium carbide is pure $(Ta, Nb)_2O_5$, which is mixed with carbon, usually in the form of carbon black, and reacted at 1600 –1800 °C. Tantalum carbide improves the toughness and resistance against thermal fatigue of cemented carbides. If the carbides are only to be used for turning operations, the tantalum carbide can be replaced with a higher percentage of niobium carbide. The metal-cutting properties of some milling cutting tools are, however, impaired by higher niobium carbide contents.

Mixed Carbides. The mixed carbides (Ta, Nb, Ti, W) C are often used. They are usually manufactured in the same way as the pure carbides. However, they can also be produced by the "menstruum" process, developed by Kennametal Inc. [33] (USA). This special method involves carburization in molten nickel, which promotes diffusion. Very pure, rather large carbide crystals are then isolated from the reaction products by treatment with acid.

Cobalt and Other Binder Metals. Cobalt powder suitable for the manufacture of cemented carbides is produced by reducing cobalt oxide, carbonate, oxalate, or formate with hydrogen at 600 – 800 °C. The powder must be very fine (1 – 5 µm) and free from impurities. Coarser cobalt powder causes local cobalt enrichment in the cemented carbides.

Nickel, iron, and chromium are rarely used as binder metals. However, nickel and chromium give corrosion-resistant products (see Section 2.3). Many attempts have been made to find a substitute for cobalt, but without success. All other metals are difficult to process and confer inferior properties in the cemented carbide.

2.1.2. Powder Batch Manufacturing

The powdered carbides, binder metals, and carbon are weighed. The mixture is then wet ground and agents are added to aid pressing. Subsequent drying and granulation give a powder batch ready for pressing and forming.

Grinding. Wet grinding converts the powder mixture into a very fine, intimate dispersion. An organic liquid milling medium (e.g., a hydrocarbon, alcohol, or acetone) prevents both reagglomeration and oxidation of the powder.

Early ball mills had a capacity of 5 – 10 L but have been replaced by mills with over 100 L capacity, and by vibration mills and attrition mills (→, Chap. 3.2.2.Size Reduction).

Drying. The slurry obtained after grinding is sieved and the liquid medium usually is removed by distillation. Thus, the liquid can be recovered in a pure state and reused. The powder must have good flow properties to allow the automatic mold-filling equipment to operate smoothly. To achieve this, the powder is formed into granules

with the aid of paraffin wax or poly(ethylene glycol). Simultaneous drying and granulation in a spray dryer are very economic.

2.1.3. Pressing and Forming

Presintered shapes are formed by various pressing methods followed, if necessary, by machining.

Direct Pressing. About two thirds of all cemented carbide products are directly pressed into the required shapes using a suitable die in a mechanically or hydraulically operated automatic press.

Extrusion. Rods, bars, and tubes can be formed with the extrusion presses commonly used in the ceramic industry. Further additives such as paraffin wax or poly(ethylene glycol) are required to produce a formable plastic mass that can flow and be extruded through suitably shaped cemented carbide nozzles.

Cold Isostatic Pressing. Large cemented carbide components of simple geometry are often cold isostatically pressed, presintered, and then machined. The carbide powder is compressed in a sealed leakproof tube on all sides by a liquid (usually water) at high pressure (ca. 200 MPa).

Indirect Forming. A large demand exists for components that do not justify the high cost of pressing equipment either because of their complicated shape or the small number required. Such components must be formed by machining pressings of a suitable shape or pieces cut from large, cold isostatically pressed bodies. The articles are first presintered to increase their strength by heating to 700 – 900 °C in hydrogen or vacuum. The pieces are then machined with diamond tools. The powder produced during machining is carefully recovered, if possible sorted into grades, and reused.

2.1.4. Sintering

The final sintering causes linear shrinkage of about 18 – 25 % in each direction resulting in a 40 – 50 % decrease in volume. The "green" pressed shapes are placed on graphite plates for sintering which is usually performed in a vacuum, less often in a hydrogen atmosphere. In modern furnaces, the pressed shapes can be directly sintered without a presintering stage. This vaporizes the wax additives used for pressing, which are then trapped in a wax separator. Despite technical improvements, the sintering step has a great influence on the quality of the end product. The carbon balance, which is so important for the properties of the product (see Section 2.3), depends not only on the carbon concentration of the powder but also on the sintering conditions (temperature, time, residual gas composition, nature of the supporting surface, and degree of filling of the furnace).

2.1.5. Machining

Although the sintered part is already fairly accurately shaped, final shaping with diamond tools or spark erosion is often necessary. The latter process allows the production of complex shapes (e.g., with holes or complex contours) that cannot be obtained directly by pressing. Surface roughness is removed by grinding, and closer dimensional tolerances can be achieved by this means in comparison with dimensional tolerances obtained after sintering.

2.1.6. Coating

Figure 4. Multilayer wear-resistant coating (total thickness ca. 8 µm) on cemented carbide substrate
a) Oxide layers; b) Ti(C,N)-containing intermediate layers; c) TiC – Ti(C,N) underlayer

Table 2. Commonly used combinations of wear-resistant coatings with cemented carbide substrates [34]

Substrate	Wear-resistant coating							
(cemented carbide) *	TiC	TiN	TiC – Ti(C,N) – TiN	TiC Al_2O_3	TiC – Ti(C,N) – TiN Al_2O_3	Al_2O_3	HfN	Al – O – N
M 15	+		+	+	+	+	+	+
P 25		+	+				+	
P 40	+		+					
K 10	+	+	+			+		+

* For explanation of designations, see Table 3.

The wear resistance of cemented carbide articles is increased by applying thin, hard coatings of TiC, TiN, Ti(CN), Al_2O_3, or other hard materials. The usual coating methods are chemical vapor deposition (CVD) or physical vapor deposition (PVD) (→Thin Films). Deposition temperatures for CVD are ca. 1000 °C, but for PVD they can be under 400 °C. Multiple coatings of layers of various hard materials are now common (Fig. 4). The total coating thickness seldom exceeds 10 µm. The particular combination of coating materials used depends on the nature of the cemented carbide substrate (Table 2) and the particular application.

2.1.7. Testing and Quality Control

Throughout its manufacture, the cemented carbide is subjected to metallographic, dimensional, physical, and chemical tests. Many of these are standardized (in Europe according to ISO and DIN standards and, in the United States, according to ASTM). Users of cemented carbides measure the following important parameters (ISO 4498):

Compressive strength:	ISO 3326
Density:	ISO 3369, ASTM B 311-58
Rockwell hardness:	ISO 3738, ASTM B 294-76
Vickers hardness:	ISO 3878.

Other determinations are sometimes carried out, e.g., of microstructure (ISO 4499, ASTM B 657-79) and of porosity and free carbon (ISO 4505, ASTM B 276-79).

The coercive force is a sensitive indicator of the structure of the material and is strongly influenced by changes in the grain size of the WC, an important factor in determining the cutting performance. The metal-removing capacity is an important parameter for the user and is usually determined by means of short duration cutting tests simulating practical conditions. The various performance characteristics of wear-resistant parts for other applications can usually only be assessed while they are in service.

2.2. Commercial Grades

The existence of many types of cemented carbides differing in composition and properties has led to a considerable broadening of their field of application, but also to a confusing multitude of products. In order to simplify the selection of a product for a particular application, various classification systems have been devised.

DIN 4990. The first standardization system was established in Germany, leading in May 1942 to the publication of DIN 4990. A color code was used to indicate different types of brazed tools.

United States. Here the Industry Code is used, and sometimes also the Buick Code, developed by the Buick Motor Division of General Motors [30].

ISO. The International Standardization Organization (ISO) began to concern itself with cemented carbides in the mid 1950s. By this time the DIN 4990 was not adequate for the classification of the newly developed universal cemented carbides for cutting cast iron and steel. The color system had also become increasingly confusing. The identifying colors blue, yellow, and red were then allotted to the metal-cutting groups P, M,

Figure 5. Vertical section of W – C – Co ternary-phase diagram at 16 % Co [35]
β = solid solution of W and C in Co; η = embrittling η-phase (W_6Co_6C); C = carbon

and K [30]. These main groups were subdivided into application groups by means of two-digit numbers whose value indicated the toughness of the carbide material. Higher values indicated higher toughness to suit the requirements both of the metal to be cut and the working conditions, with higher feed rates and lower cutting speeds. Lower values correspond to better wear resistance at the expense of toughness and higher cutting speeds. Thus, high numbers indicate high toughness and low index numbers indicate harder, more wear-resistant materials (Table 3).

The *World Directory and Handbook of Hardmetals* gives collected data on cemented carbides in tabular form [30]. The various products available under each ISO classification are listed for comparison to facilitate product choice.

Great Britain. In 1967 the British Hardmetal Association (BHMA) brought out a classification system based on hardness, transverse rupture strength, and titanium and tantalum carbide contents as a measure of crater wear resistance. This system has not been used outside Great Britain and has found little acceptance even there [30].

2.3. Properties

The important application properties and the manufacturing techniques for WC – Co cemented carbides are dictated by the ternary-phase diagram for W – C – Co (Fig. 5) [34]. The important region for both production and properties is that marked WC + β (solid solution). Cemented carbides for industrial use must have a composition lying within this region, which is ca. 0.1 wt % C "wide." Carbon deficiency (undercarburization) causes the appearance of the η-phase and hence embrittlement. An excess of carbon (overcarburization) separates out as finely divided graphite.

The transverse rupture strength is an important parameter in practice. It reaches the maximum in the binary-phase region and is reduced by the appearance of the η-phase or by the precipitation of a graphite phase. However, hardness increases with undercarburization (Fig. 6).

The "art" of manufacturing cemented carbides depends on the control of the carbon balance. Other important properties of cemented carbides in comparison with tool steels and other hard materials are given in Table 4. Cemented carbides with a cobalt binder are generally not resistant to corrosion. Even aqueous solutions

can attack the binder phase by the formation of the local galvanic elements. The relative corrosion resistance of cemented carbides containing cobalt, nickel, and nickel – chromium binders is shown in Table 5. A nickel – chromium binder gives acceptable corrosion resistance [37]. Resistance can be further improved by using a high content of Ta – Nb carbides, which are highly corrosion-resistant ceramic carbides [38].

Figure 6. Rockwell hardness (R_A) and transverse rupture strength of WC – Co cemented carbides as a function of carbon content of the cemented carbide [36]
a) Transverse rupture strength; b) Rockwell hardness

2.4. Uses

About 50 – 60 % of cemented carbides has always been used for cutting. Only 8 – 10 % is employed in forming equipment (wire-drawing dies, press dies, rolls, etc.) although this proportion is increasing. The mining industry, building industry, and road and tunnel construction account for a further 20–25 %. The remainder (10 – 12 %) is used for components subjected to wear, such as grinding balls, sealing rings, plungers, grinding tools in size reduction equipment, spikes, and equipment for manufacture of synthetic diamonds.

Wear-resistant components used in the chemical industry must be constructed from corrosion-resistant cemented carbides. The corrosion-susceptible cobalt binder is replaced by Ni, Ni – Cr alloys [37], or noble metals (Pt) in these products, such as the mass-produced cemented carbide seal rings shown in Figure 7.

Figure 7. Cemented carbide seal rings for corrosive chemical environments

2.5. Economic Aspects

Although the production of cemented carbides is small in comparison to that of steel (Table 6), these products have achieved great economic importance because they have improved the productivity of cutting and forming processes. This is illustrated in Figure 8, which shows the enormous increase in cutting speeds that followed the introduction of cemented carbides. Results for other cutting materials are shown for comparison. The newer materials (e.g., ceramics, polycrystalline diamond, and cubic boron nitride) have produced further increases in cutting speeds.

Table 6. Estimated annual world production of hard metal and steel [31]

Year	Estimated production,	
	Cemented carbides, 10^3 t/a	Steel, 10^6 t/a
1950	1.1	190
1960	2.3	330
1965	4.5	447
1970	12.0	597
1975	18.0	680
1980	24.0	710
1985	30.0	750

World production of cemented carbides is divided about equally among the United States, Europe (excluding the former Soviet Union),

Table 4. Properties of important cutting materials [31]

Property	High-speed steel	Cemented carbides	TiC based cemented carbides	Ceramics (oxides, nitrides)	Polycrystalline cubic boron nitride	Polycrystalline diamond
Density, g/cm^3	8.0 – 9.0	9.0 – 15.0	5.0 – 9.0	3.2 – 5.0	3.45	3.5

2.6. Toxicology

Losses must be avoided in the processing of very fine dust consisting of hard material (carbide), cobalt, and cemented carbide. Loss of dust represents not only an economic loss but also a danger to health, and must be prevented by means of dust extraction equipment, filters, and masks. The adverse effects of the dust have been the subject of numerous investigations [39–42].

Figure 8. Increase of cutting speeds for various materials as a result of the progress in cutting materials [31]
a) Carbon steel; b) Alloyed tool steel; c) High-strength steel; d) Cemented carbide; e) Oxide ceramics; f) Mixed ceramics; g) Coated cemented carbide; h) Cubic boron nitride; i) Polycrystalline diamond; j) Silicon nitride

The toxicity of cemented carbides is primarily a function of the cobalt content, but the carbides can also form chemically inert deposits in the lungs that are not degraded or eliminated by the body. Diseases caused by emented carbides are associated with the presence of cobalt in the blood and other organs. However, the predominant illness is fibrosis of the lungs, which reduces their performance. If exposure to the dust ceases during the early stages of the disease (e.g., by a change of work environment), rapid abatement of the symptoms usually results. The TLV value for cobalt is 0.1 mg/m^3 at present, although this may be reduced to 0.05 mg/m^3. For tungsten, tantalum, and their insoluble compounds, the corresponding value is 5 mg/m^3. Regular medical checkups are required for workers in contact with cemented carbide dust [43].

Toxicity problems can also arise where cemented carbides are processed by the user [44]. Wet grinding may produce dangerous concentrations of cemented carbide material in the form of aerosols.

Domestic heating oil (domestic fuel oil, industrial gas oil) is an extra-light liquid distillate fuel produced from crude oil in refineries. In some countries a certain percentage of fatty acid methyl ester (FAME) can be included. This fuel is used for commercial and industrial processes, and mainly for heating purposes in working areas and domestic accommodation. The fuel is burned in atomizing or vaporizing burners.Domestic heating oil is a very common energy carrier in the domestic heating market of many European countries, in Northern America, and in Japan. As a result of emission legislation and technical requirements different products are available in different countries. Basically heating oils can be divided in three classes:1. Kerosene, 2. Standard heating oil, 3. Low-sulfur heating oil.The large volume and share of industrial gas oil in the total refinery stream (20 to 30 %) makes this product economically significant.

1. Domestic Heating Oil

Domestic heating oil (domestic fuel oil, industrial gas oil, Heizöl EL) is an extra-light liquid distillate fuel produced from crude oil in refineries (see → Oil Refining). In some countries the product can contain a certain percentage of fatty acid methyl ester (FAME). This fuel is used for commercial and industrial processes, and mainly for heating purposes in working areas and domestic accommodations. The fuel is burned in atomizing or vaporizing burners.

The first industrial applications of heating oil were reported at the beginning of the 20th century. In the United States, industrial gas oil was being used to produce hot water and steam for residential heating as early as the 1930s. The major expansion of domestic heating oil and oil firing in Europe has occurred since the end of the 1950s. Today domestic heating oil and natural gas (in some countries electricity) are the most common energy carriers in the domestic heating market of many European countries, in Northern America, and in Japan. Due to emission legislation and technical requirements different products are available in different countries. Basically heating oils can be divided into three classes:

1) Kerosene
2) Standard heating oil
3) Low-sulfur heating oil

The large volume and share of industrial gas oil in the total refinery stream (20 to 30 %) makes this product economically significant.

1.1. Composition

Domestic heating oil is an extra-light liquid fuel composed almost entirely of paraffinic, naphthenic, and aromatic hydrocarbons. In addition to these hydrocarbons, it contains small quantities of sulfur compounds and still smaller (ppm) amounts of nitrogen and oxygen compounds. Since the beginning of the 21st century special heating oil qualities have been developed, which are almost free of sulfur and nitrogen. The chemical characterization of the fuel is limited to group analysis by classes of compound. The product structure depends on the origin of the crude oil and the processing employed. The elemental composition, however, does not vary significantly. The boiling range is between 160 and 390 °C (kerosene: 300 °C). A typical domestic heating oil has the elemental composition given in Table 1.

Table 1. Elemental composition of a typical domestic heating oil

Element	Concentration
Carbon	86.5 mass %
Hydrogen	13.3 mass %
Sulfur	< 0.2 mass %
Nitrogen	50 – 400 ppm
Oxygen	traces

1.2. Quality Aspects

Quality aspects are mostly described by physical parameters or special test methods for mineral oil products. Basically for all three different qualities (kerosene, standard heating oil, low-sulfur heating oil) the requirements can be classified as follows.

1) Requirements due to national legislation (tax, etc.)
2) Requirements because of the climatic situation
3) Performance parameters with similar test methods and limits in different countries
4) Performance parameters, where national limits vary in a wide range
5) Performance parameters, where test methods and limits have to be developed and/or harmonized

Density. The density depends on temperature and for heating oil is specified at 15 °C. Density alone is of little significance as an indication of the burning characteristics of heating oil in modern atomizing type burners. However, in vaporizing-type burners soot and CO emissions frequently increase when fuels are used whose density and viscosity are close to the specified limits. That is the reason why in some countries (UK and Japan) kerosene with its lower density and boiling range is used as heating fuel for vaporizing-type burners. Density limits vary in a wide range from country to country. When used in conjunction with other properties the density is of value in mass – volume relationships and in calculating the specific energy (heating value, net calorific value) of an oil.

Net Calorific Value. The net or inferior calorific value H_i (MJ/kg; synonymous with lower heating value, see → Gas Production, Chap. 8.2.1.1) does not vary significantly between different heating oils. H_i can be calculated from the density at 15 °C (d_{15}, kg/m^3) and the sulfur content w(S) (mass %):

$$H_i = 52.92 - 11.93 \times \frac{d_{15}}{1000} - 0.29 \times w\,(\mathrm{S})$$

Viscosity. Viscosity limits are specified to help maintain uniform fuel flow in appliances with gravity flow, and to provide satisfactory atomization and constant flow rate through the small nozzles of domestic burners. A viscosity of 2.5 to 3 mm^2/s is needed for good spray formation in conventional atomizing burners. This can be achieved by preheating of the oil to a temperature of 60 °C maximum. At the same time, the oil throughput in a conventional nozzle is reduced by preheating because of thinner film formation in the nozzle itself. The effect of temperature on viscosity is shown in Figure 1.

Figure 1. Effect of temperature on viscosity

Distillation. The distillation test shows the volatility of a fuel and the ease with which it can be vaporized. It is of greater significance for oils that are to be burnt in vaporizing type burners than for those burnt in the atomizing type. For example, a low 10 % value assures easy starting of a vaporizing type burner. Nevertheless, a homogeneous distillation curve is necessary to reduce emissions of CO and soot. A typical distillation curve of a domestic heating oil is depicted in Figure 2. Kerosene type fuels however vaporize at significantly lower temperatures.

Figure 2. Typical distillation curve of domestic heating oil

Flash Point. The flash point of a fuel is an indication of the maximum temperature at which it can be stored and handled without serious fire hazard. The minimum permissible flash point is usually regulated by law and can therefore differ from country to country.

Sulfur Content. The sulfur content is usually limited by national legislations. The sulfur content in domestic heating oil has been reduced significantly over the years. In Europe an EC directive allows sulfur content to be as high as 0.2 %. This value is reduced to 0.1 % starting from 2008. The amount of low-temperature corrosion products formed in modern energy efficient boilers can be influenced by the sulfur content of the oil. In condensing boilers which is the most efficient burner technology but not very common for domestic heating oil in contrast to natural gas equipment — the pH value of the condensate depends on the sulfur content. To promote these energy saving appliances in many countries a second quality with significantly lower sulfur content has been introduced to the market and standardized.

Low-Temperature Behavior. In heating oil crystallization of high molecular mass *n*-paraffins (waxes) can occur at low ambient temperature. The wax crystals can block fuel pipes and especially the fuel filter. Three test methods are used to assess the low-temperature behavior.

Pour Point. The pour point gives the lowest temperature at which a fuel oil can be stored and still is capable to flow under very weak forces. The determination of the pour point alone is not sufficient to assess the cold flow behavior in practical application.

Cloud Point. The cloud point is the temperature at which heating oil begins to become turbid at a defined cooling rate because of the formation of small wax crystals.

Cold Filter Plugging Point (CFPP). The CFPP is the temperature at which, under defined conditions, a heating oil sample can no longer pass a defined filter within a specified time. The CFPP can be improved by additives (see Section 1.3.2). Neither cloud point nor cold filter plugging point alone can sufficiently describe the cold flow behavior in real installations but the combination of both does.

Carbon Residue. The carbon residue of a fuel is a measure of the carbonaceous material that is left after all volatile fuel components are vaporized in the absence of air. It is a rough approximation of the tendency of a fuel to form deposits in vaporizing burners where the fuel is vaporized in an air-deficient atmosphere. To obtain measurable values of carbon residue in the lighter distillate heating oils, first 90 % of the oil must be removed by distillation, then the carbon residue concentrated in the remaining 10 % bottoms is determined.

Ash. The amount of ash is the quantity of noncombustible material in an oil. The amount of ash in domestic heating oil is almost zero if heating oil directly from the refinery is investigated. However, traces of metals can be found in heating oil, as steel equipment is mainly used for transportation and storage [1].

Water and Sediment. If a domestic heating oil contains appreciable amounts of water and sediment this will lead to fouling of facilities for handling the oil, and difficulties in burner mechanisms will arise. Sediment may accumulate in storage tanks and on filter screens or burner parts, resulting in obstruction to flow of

oil from the tank to the burner. Water in distillate fuels can cause corrosion of tanks and other metal equipment.

Storage Stability. The aging of domestic heating oil is caused by oxidation and radical polymerization reactions, which cause darkening and then sediment formation. The phenomenon of natural aging of middle distillates has been treated in many publications. However, a comprehensive, detailed and consistent theory of the aging mechanism was not found so far. A detailed summary of more than 330 publications dealing with stability of middle distillates is given in [2].

The following items can deteriorate the stability of domestic heating oil:

Heat
Light
Oxygen
Catalytic effects of metals (copper)

Thermal Stability. If the thermal stability of a heating oil is not sufficient, deposits may be formed in hot spots in the burner — usually between the oil preheater and the nozzle. In modern burners with reduced NO_x emissions and low throughput, temperatures significantly higher than 100 °C have been measured after shut-down of the burner. This is due to back radiation from the heating chamber. It is known from many laboratory tests that the aging process (sediment formation) of the oil increases significantly between 100 and 120 °C. To circumvent this, burner manufacturers tend to develop burners with maximum temperature of 100 °C especially after shut-down of the burner. If the oil contains copper ions, the thermal stability of the fuel is reduced by approximately 20 K. A new laboratory test to assess the thermal stability of a fuel has recently been developed in Germany [3].

Lubricity. As sulfur components contribute to the lubricity of the fuel, problems may occur with desulfurized heating oil qualities. Therefore lubricity requirements have been implemented in some standards for low-sulfur heating oil.

1.3. Production

1.3.1. Product and Processing

Since the early 1970s, production of petroleum-based products has been influenced by an increasing range of crude oils used and by a restructuring of refinery production facilities.

There is a persistent trend towards minimizing the amount of residual products and maximizing the quantity of middle distillates and gasolines. This change has become possible as the following equipment has been incorporated in the refinery process:

1) Vacuum distillation equipment,
2) Thermal gas-oil units,
3) Catalytic crackers, and alternatively
4) Hydrocrackers.

To reduce the sulfur content of domestic heating oil, hydrodesulfurization equipment has been installed in many refineries. A simplified flow diagram of the production of domestic heating oil is given in Figure 3. The following distillation cuts are the main components for the blending of heating oil:

1) Kerosene
2) Light gas oil (LGO)
3) Heavy gas oil (HGO)
4) Hydrodesulfurized gas oil (HDS-GO)

The necessity and extent of blending domestic heating oil from different components depends on the crude oil or the mixture of crude oils employed, on the refinery facilities and the product mix that has to be achieved, and on the specifications which have to be met.

1.3.2. Upgrading with Additives

Product quality and application requirements can quite often only be met by employing special purpose additives, which are added to the final product in the required concentrations. Some types of additive are usually introduced into the product in the refinery. The use of additives for quality improvement of heating oil is approved according to many heating oil standards. These additives may be applied in suitable concentrations, provided they are not known to exhibit any harmful side effects. Recommendations, which should help to select suited additives, are published in [4].

Figure 3. Production of domestic heating oil (simplified flow diagram)

Flow Improvers. Flow improver additives improve the cold flow properties of domestic heating oil. These additives are added to the product stream in many refineries. Ash-free polymers are used as flow improvers. At a temperature slightly higher than the cloud point, the additive forms crystallization nuclei, to which the wax crystals become absorbed. Further growth of the wax crystals is reduced by adsorption of the additive on the crystal surface. Thus, both the crystal size and the tendency to agglomerate are lowered. The small crystals formed pass through the filters of the heating system. Therefore, the CFPP can be lowered significantly by adding flow improvers. The dosage depends on the base fuel and on the CFPP value which is to be achieved. Typical concentrations are 50 – 500 ppm.

Flow improvers have to be added to the fuel at temperatures above the cloud point; addition after crystal formation is not effective.

Metal Deactivators. In special cases, metal deactivators are also added to industrial gas oil to attain long-term storage stability of more than three years. The negative influence of copper [5, 6] on storage stability can be reduced by these additives.

Other types of additives are sometimes introduced into the customer's storage tank but not into the fuel in the refinery.

Combustion Improvers. The purpose of these additives is to suppress carbon formation during combustion. Combustion improvers are predominantly organometallic compounds, ferrocenes have proved particularly effective in domestic heating oil. Although burner technology has advanced considerably with respect to near-stoichiometric combustion with low carbon formation, combustion improvers can still effect and stabilize optimal combustion over long periods. The application of combustion improver additives is not necessary in modern blue flame burners with reduced NO_x emissions.

Additives for Increased Storage Stability. The application of metal deactivators and antioxidants can improve the storage stability of the fuel. The importance of these types of additives is increasing because the average storage time of heating oil in domestic storage tanks increases due to reduced oil consumption (higher efficiency equipment, better insulation of houses) while the size of the storage tanks has been kept constant.

Reodorants. Some additive packages contain reodorants to improve the odor of heating oil. The unpleasant smell is caused particularly by certain sulfur-containing and unsaturated components. If there is no leakage in the oil heating system, the application of reodorants is not necessary.

Biocides. In some cases water can be found in the bottom of storage tanks. Conditions at the interface between water and oil allow the growth of microorganisms. The result is very often sediment formation. The addition of suitable biocides stops the growth of microorganisms but the best way is to remove water regularly from the bottom of the tank.

1.4. Uses and Heating Efficiency

Domestic heating oil is mainly burnt for heating purposes and for the heating of drinking water in burner/boiler systems. The substantial rise in energy prices, the growing awareness of air pollution and the international discussion on greenhouse gases have changed the assessment of heating systems. It is possible to save a lot of energy in the domestic heating sector if modern heating systems replace the old-fashioned systems.

A modern heating system has to fulfill the following demands:

1) Minimal pollutant load on the environment
2) Optimal matching of capacity to demand
3) High efficiency on an annual basis
4) Reliable operation
5) Comparatively attractive product prices
6) Compliance with all standards
7) Long-term availability of the energy source employed

The pollution of the environment could be reduced considerably by development and installation of more efficient heating systems (reduced oil consumption) and of low-emission burners. Generally, the fuel is evaporated to a spray before combustion. In modern low-emission burners, up to 30 % of the flue gas is recycled to the fuel spray. The partial pressure of oxygen and the maximum temperature in the flame is reduced by this technology which allows to meet strict NO_x emission limits. As the oil spray is completely vaporized before it reaches the combustion zone, the formation of soot and particulate matter emission (PM10) can be avoided. Thus, similar advantages as in the combustion of natural gas can be achieved. A good summary of basic knowledge for air-fuel mixing, evaporation and combustion technology with special regard to liquid fuels is given in [7].

Since investments like improved thermal insulation in existing buildings and especially the better insulation standards of new buildings gave the expected energy saving, oil burners designed for lower throughput have been developed. In new buildings the heating system is often dimensioned according to the demand of hot drinking water rather than by the demand of space heating. The minimum power for conventional pressure jet burners is 15 kW (ca. 1.5 L/h) because of the dimension of the nozzle. Other spray formation systems have been developed to allow the construction of burners with reduced throughput. However, not many of these systems have been installed yet.

The boiler efficiency on an annual basis has been improved significantly during the last 25 years by better insulation of the boiler walls, reduced internal cooling loss and by reduction of the flue gas loss. The annual efficiency of a modern low-temperature burner – boiler unit is more than 93 % (basis: net calorific value). The radiation loss and the internal cooling loss account for less than 1 % each, while the flue gas loss is influenced by the flue gas temperature and the amount of excess air.

To maximize the efficiency condensing boilers have been developed. The annual efficiency of condensing boilers is between 100 and 103 % (basis: net calorific value). The market share of condensing boilers differs from country to country but it is steadily increasing. The construction and materials used in condensing boilers are very much dependent on the fuel specification, especially the sulfur content. If the sulfur content is below 50 ppm, it is possible to use similar heat-exchanger materials as in gas condensing boilers. If the sulfur content is higher, the materials used in the condensing areas of the boiler and the flue gas pipe have to be specially resistant to corrosion by acidic condensate. The pH value of typical condensate varies from 2 to 3 depending on the construction of the burner and boiler, the sulfur content of the fuel and the amount of condensate [8]. For low sulfur heating oil the pH value is between 2.8 and 4, which is similar to gas condensing boilers [9].

In some countries the basis for the calculation of the flue gas loss is the gross calorific value of the heating oil, in other countries the calculation is based on the net calorific value. In the latter case, the flue gas loss can be calculated from the

difference in temperature between flue gas and ambient air (ΔT) and the concentration of CO_2 or O_2 in the flue gas:

$$\text{flue gas loss} = \Delta T \left(\frac{0.5}{[CO_2]} + 0.007 \right)$$

or

$$\text{flue gas loss} = \Delta T \left(\frac{0.68}{(21 - [O_2])} + 0.007 \right)$$

These formulae cannot be used for condensing boiler technologies because the latent heat of condensation of the water (produced in combustion) is utilized in addition to the sensible heat. Therefore, the flue gas loss and the efficiency of a boiler should be calculated with the gross or superior calorific value, H_s (synonymous with higher heating value, see → Gas Production, Chap. 8.2.1.1). The flue gas loss can be taken from Figures 4 and 5.

Figure 4. Flue gas loss (basis: net calorific value)

Figure 5. Flue gas loss (basis: gross calorific value)

Domestic heating oil is used in *small power stations* (with Diesel engines) for simultaneous production of electricity and hot water or steam for heating purposes [10]. In research projects and pilot applications domestic heating oil has been used to produce hydrogen and carbon monoxide as feedstock for high temperature fuel cells [11].

1.5. Product Specifications

There is no international or European standard for domestic heating oil. The minimum requirements of domestic heating oil in some national standards are given in Table 2 and 3. Some countries have introduced standards which differ mainly in sulfur content. Other countries have set different limits for cold flow properties in winter and summer. Generally the lighter qualities (e. g. kerosene type fuels, Grade 1 in USA) are specially suited for vaporizing burners.

In 2003 a new European Standard (EN 14213) has been published. This standard specifies requirements and test methods for marketed and delivered fatty acid methyl esters (FAME) to be used either as a heating fuel at 100 % concentration, or as a blending component for the production of heating fuel. However, mixtures have not been standardized yet. An increasing demand for bio-fuels as components of automotive fuels can be observed especially in Europe. As in some countries the logistics of diesel and heating oil are not completely separated, it has to be specified to what extent FAME is allowed to be a component of heating oil.

1.6. Storage and Transportation

A particular characteristic of domestic heating oil is the flash point, established at > 55 °C. This value leads to classification of the fuel in Hazard Class III A (GefStoffV). There are no special safety restrictions concerning storage or transportation of the product.

During transportation and storage domestic heating oil has to be kept at such temperatures that the sedimentation of wax crystals is avoided. Therefore the cold flow behavior of the fuel has to be considered for storage and transportation. This can be a problem especially in underground storage tanks, when the pipes to the burner are not sufficiently insulated. In Germany the storage temperature must be above 0 °C. Lower tem-

peratures are allowed if a special fuel with satisfactory low temperature-properties is used.

1.7. Environmental Protection

The importance of the *sulfur content* of domestic heating oil for the consumer lies in the emission of sulfur dioxide and thus the problem of environmental pollution. In the EU, the sulfur content of domestic heating oil is now limited to 0.2 mass % (Austria 0.1 mass %). The EU-sulfur directives (1999/32/EC) requires to reduce that limit to 0.1 mass % by 2008. In some countries or regions there are special fuels available with sulfur content < 0.05 mass % or even < 50 mg/kg (0.005 mass %, low-sulfur heating oil). In general the average sulfur content has been decreasing continuously.

Further reduction of the sulfur content of the fuel and thus reduced SO_2 emissions when burning the fuel can be accomplished with desulfurization processes, if these facilities are available in the refinery. However, removal of sulfur requires hydrogen and is performed at pressures of 2.5 to 7 MPa with the result of increased energy consumption and CO_2 emissions. On the other hand this is more than compensated by higher annual efficiencies of low temperature or condensing boilers, because fouling of the heat exchanger surfaces is reduced.

The *nitrogen content* of domestic heating oil is not specified in national standards. It depends on the crude oil and the processing employed. Some desulfurization processes may also reduce the nitrogen content of the fuel. Typically, the nitrogen content is between 50 and 200 mg/kg, occasionally it can be as high as 400 mg/kg. For

low-sulfur heating oil or kerosene the nitrogen content often is below 50 mg/kg. The fuel nitrogen contributes to the emissions of nitrogen oxides (NO_x) during combustion. 50 to 100 % of the fuel nitrogen are converted to NO_x depending on the type of burner [12].

Typical emission levels for oil heating (Table 4) are dependent on the technology employed [13]. As could be expected, modern boiler and burner technology results in lower emission values of CO, NO_x, and particulate matter (PM10) than older technologies.

The emissions of components that are traditionally not determined have been investigated [14]. The study encompasses emissions of N_2O, methane, benzene, toluene, xylene, and PCDD/PCDF (polychlorinated dibenzo-*p*-dioxin/dibenzofuran). The emission levels of these components are very low. Oil-fired systems do not contribute significantly to total emissions of these components.

The emissions of NO_x and SO_2 could be reduced by secondary treatment of the flue gas. The technology for that flue gas treatment is available on the market but is usually not used for domestic installations, because the emission limits can be met by modern combustion systems alone.

Recently particulate matter emissions have become more important. It is well accepted that with modern combustion technology in which the fuel is evaporated before being combusted the particulate matter emissions are similar to those of gas appliances.

1.8. Economic Aspects

The consumption of heating oil in selected countries is given in Table 5 [17]. The sizes of the US market and the Japanese market are similar to the market in Germany. Market data are available on www.euro-fuel.net. Data for the US market can be taken from [15].

The consumption of heating oil has been decreasing in many countries. This is caused by better insulation of houses and more efficient boiler systems and by the fact that in some countries oil heating systems have been switched to other systems. In many countries natural gas is the main competitor, in other countries electrical heat-pumps are gaining market share. In contrast, in some countries the number of oil installations has increased by replacing direct electrical heating.

2. Residual Fuel Oil

Residual fuel oil (RFO) is a refinery product derived from petroleum crudes. Since the introduction of oil conversion technologies in the mid-1960s most RFO has been produced by blending vacuum distillation residues with residues from thermal crackers (e.g., visbreakers). Material with a marketable viscosity range results from further addition of catcracked components as well as gas oil fractions of varying density derived from thermal processing. Heavy oils derived from lignite and coal will not be discussed here because these are only of local interest.

2.1. Composition and Properties

Residual fuel oil is an extremely complex material as a consequence of its origin in the cracking process. In addition to paraffinic, naphthenic, and aromatic hydrocarbons (some with molecular masses approaching 20 000), RFO contains nitrogen and oxygen compounds as well as organometallic substances that contribute to its ash content. A typical elemental analysis shows a distribution (in wt %) of 87.5 % C, 10.6 % H, 1.8 % S, and 0.1 % ash (C : H ratio 8.25); these values may be assumed valid for performing combustion calculations.

RFOs are colloidal systems of highly dispersed macromolecular components (asphaltenes) in solution equilibrium with a continuous oil phase (the maltenes). Just like the maltenes, asphaltenes may be regarded as natural fuel components, although with a much higher C : H ratio. Most of the metallic ash components are present in oil-soluble form, either as porphyrins or as part of the asphaltene phase. Metal atoms are in most cases bonded to the heteroelements sulfur, oxygen, and nitrogen.

Crude oil is separated into its various fractions by fractional distillation, so RFO tends to be enriched in metals. The most important ash components are vanadium, sodium, and nickel, as well as calcium and magnesium (all in the

ppm range). The metal content depends on the geographic origin of the crude oil (see Table 6).

Numerous other metals are present in trace amounts (µg/kg), but may be ignored for commercial applications. Most metal analyses today result from X-ray fluorescence determinations performed directly on the RFO.

The principal distinction between RFO and domestic heating oil is that the former must be preheated prior to use. Compared to coal, RFO offers the advantages of relatively straightforward handling, favorable burning characteristics, and a high specific heat content. Furthermore, the relatively low ash content of RFO largely eliminates problems related to the disposal of ash and filter dust.

2.2. Production

Depending on the proposed application, RFO components as described in Section 2.1 are blended in the refinery to meet appropriate product specifications. The characteristic that most

clearly distinguishes one grade of RFO from another is nominal viscosity at 100 °C (or 80 °C in English-speaking countries). Rheologic factors preclude the use of 50 °C viscosity data.

Standard grades of RFO for steam boilers and industrial furnaces have viscosities of 20 – 50 mm^2/s, whereas the marine market prefers material in the 10 – 55 mm^2/s range (all at 100 °C). Viscosities between 100 and 3000 mm^2/s are typical for oil gasification units and for internal use within a refinery.

Economic considerations are responsible for the fact that suppliers seldom employ additives in RFO. Additive addition remains the responsibility of the end user, and is limited to metalcontaining, oil-soluble substances that improve combustion characteristics (e.g., particulate control by suppressing soot formation) and minimize low-temperature corrosion at cold junctions (through dew-point reduction). Compounds of magnesium and other alkaline earth metals are occasionally added to raise the melting point of the ash.

2.3. Uses

The most important uses of RFO have already been noted in Section 2.2. On a world basis, most of the product is used in steam generators and industrial furnaces (ca. 400×10^6 t/a) or marine applications (85×10^6 t/a). Currently, RFO represents ca. 20 – 22 % of the "cut of the barrel" (based on data from the Western world), though demand in the industrialized countries is diminishing. Interest in RFO as a tuyere-injection "reducing agent" for blast furnaces varies according to the coal – residual oil cost ratio, because from a technological standpoint the two materials can be regarded as equivalent. Increasing application of oil conversion technologies coupled with environmental factors suggests that consumption of RFO in the industrialized nations will continue to decline relative to so-called "white products" (middle distillates and gasoline). The following market share figures (RFO as a fraction of total oil consumption) for 1988 provide additional insight: United States, 9 %; Federal Republic of Germany, 10 %; France, 13 %; United Kingdom, 29 %; Japan 31 %.

Usually RFO is combusted in furnaces with any of several types of burners that are distinguished by the method employed for atomization. The most important types are:

1) Jet atomizers of the nozzle or lance type (operating pressures up to 4.0 MPa, atomizing viscosities of ca. 10 mm^2/s, preheating to 140 °C)
2) Rotary cup burners (0.5 MPa, ca. 15 – 25 mm^2/s, 110 °C)
3) Air or steam atomizers (operating parameters analogous to rotary cup burners, air or steam flows of 5 – 7 wt % relative to fuel throughput)

The choice of burner type depends on the design of the combustion facility. Key factors include adequate residence time for combustion of the asphaltenes and low specific heat load, together with near-stoichiometric combustion to minimize NO_x emission.

Some marine users of RFO continue to employ steam boiler – turbine combinations, although diesel engines now account for 96 % of the market worldwide, and their use continues to increase. Diesel engines are clearly more economical to operate than turbines, especially under partial load conditions. With the aid of turbocharging and waste heat recovery, a maximum thermal efficiency of ca. 50 % can now be achieved at a specific fuel consumption as low as 150 g/kWh. Today's RFO can be utilized without difficulty in both 4-stroke trunk piston engines (minimum output: 160 kW per cylinder at 750 min^{-1}) and 2-stroke cross head engines (maximum output: 3500 kW/cylinder at 80 min^{-1}). Pretreatment of RFO for use as a motor fuel entails centrifugal separation (purifier/clarifier) and fine filtering (10 – 20 µm). In addition, effective preheating is necessary (to 160 °C with an injection viscosity of 9 – 12 mm^2/s and an injection pressure ahead of the jet of as much as 140 MPa). Taken together, these measures assure optimal combustion as well as adequate protection against abrasive wear.

2.4. Quality Specifications, Testing, and Analysis

For technological and economic reasons reliable standards must be available for RFO classification, and product specifications must be clear and acceptable to all parties involved. To date,

standards have been developed for residual fuels for *industrial uses* only on a national basis. The most important distinctions between various product grades relate to viscosity, density, flash point, and sulfur and ash content. Standards applicable within the United States are covered by ASTM-D 396–84; for the United Kingdom, BS 2869; for the Federal Republic of Germany, DIN 51063 (part 3 and, in the future, part 5, which specifies a 1 % sulfur content); for Switzerland, SN 181160/2–86; for Austria, öNORM C 1108–84; and for Japan, JIS K K 2205.

Standards for RFO intended for marine use are given in → Marine Fuels.

Analytical values for RFO vary widely depending on applicable comprehensive standards and local requirements. They are a function not only of refinery processing but also of the origin of the crude oil. Considerable progress toward uniformity has been achieved in recent years, largely because of increasing awareness and knowledge with respect to environmental protection.

Density. Density depends on temperature, thus RFO density data are uniformly reported at 15 °C to facilitate conversion of volume into the commercial measure mass (in tonnes). Industrial residual fuels are not normally subject to a density limit (typical values: ca. 995 – 1020 kg/m^3). However, density is important for marine applications (maximum 925 – 1010 kg/m^3) because it is a limiting factor in the effective use of centrifugal separators. Density is also related to aromatic content, which in turn affects ignition characteristics in a combustion or diesel engine. Further refinement of ISO 8217 is expected to result in incorporation of a density limit, particularly for material with a viscosity $<$80 mm^2/s.

Kinematic Viscosity. This parameter also depends on temperature. The reported "nominal viscosity" should be determined at a temperature of at least 80 °C, preferably 100 °C. Kinematic viscosity is important in both the industrial and marine sectors because it largely determines the level of preheating required for RFO transfer and for its input into a burner or diesel engine. Reliable and economic operation requires the availability of appropriate viscosity measurement and control systems.

Flash Point (Closed Cup). Flash point information is important in ensuring safe transport and storage. In the case of residual fuels, flash point determinations above 65 °C are normally carried out according to ASTM-D 93 (Pensky –Martens). Flash point specifications in the various norms range from a minimum of 60 °C (marine fuels) to 70 – 100 °C (inland applications).

Sulfur Content. Sulfur content is largely a function of the origin of the corresponding crude oil. Residual fuel oil desulfurization at the refinery presents serious technological problems, and is currently not economical. The sulfur restrictions imposed by various countries must usually be met by proper choice of crude oil. Low-sulfur crude is available only from a few sources (North Sea, North Africa), and for this reason has a higher market value than ordinary crude. The most important commercial RFO gradations with respect to sulfur content are 1.0, 1.5, 2.0, and 2.5 % for the industrial market, and up to 5.0 % for marine applications.

The principal problems posed by sulfur arise from its combustion products, sulfur dioxide (an environmental hazard) and sulfur trioxide (conversion rate to sulfur trioxide is 1 – 3 % because of combustion with surplus oxygen). Sulfur trioxide increases the sulfuric acid dew point in the off-gases. The resulting condensate, together with water, causes low-temperature corrosion of metallic surfaces.

Conradson Carbon Residue (CCR): Asphaltene Content. The CCR test provides insight into the tendency of a fuel to coke. In the case of RFO, this test is expected to be replaced in the near future by the Micro Carbon Residue Test (ASTM D 4530) because of the relatively wide variation in CCR test results (14 – 20 %). However, even with the expected improvement in precision and a considerable reduction in effort, the results are likely to remain of marginal value. This is because the test methods themselves are based on low-temperature *carbonization*, whereas the process that occurs in a motor or a burner is an *overstoichiometric combustion*, an entirely different phenomenon.

Asphaltene content is more significant, although it is not the subject of any standards. By definition, asphaltenes are substances that are precipitated from an oil sample by addition of a 30-fold excess of *n*-heptane, and that are soluble in pure toluene. Asphaltenes have a molecular mass in the range of 5000 – 20 000, with

particle sizes of 1 – 10 nm. Asphaltenes often agglomerate because of polar forces.

Ash Content: Catalyst Fines. The ash from a residual fuel is defined as the oxide residue remaining after complete conversion of the fuel (ashing temperature 775 ± 25 °C). The ash content of commercial RFO is typically between 0.02 and 0.1 wt %. The most important ash components from a technical standpoint are those containing vanadium, sodium, nickel, aluminum, and silicon. Sodium reacts with sulfur to produce sodium sulfate, Na_2SO_4 (*mp* 880 °C). Vanadium oxidizes to vanadium pentoxide, V_2O_5 (*mp* 670 °C). A eutectic mixture of these two compounds melts at 565 °C. In addition, provided the conditions are appropriate (e.g., a critical Na : V molar ratio in the fuel of 1 : 3), Na_2O and V_2O_5 can combine to give vanadyl vanadates. The most commonly observed forms are vanadate I ($Na_2O \cdot V_2O_4 \cdot 5\ V_2O_5$, *mp* 559 °C) and vanadate II ($5\ Na_2O \cdot V_2O_4 \cdot 11\ V_2O_5$, *mp* 577 °C). The combination of the aforementioned materials leads to deposits on the heat transfer sections of boilers and in the combustion chambers of diesel engines or turbo-chargers. Vanadate melts cause high-temperature corrosion of such thermally stressed components as superheater surfaces and exhaust valves. Countermeasures include careful choice of construction materials and appropriate component design (e.g., maximum steam temperatures in RFO-fired boilers of 540 °C, exhaust valve cooling).

Small amounts of aluminum and silicon are introduced into RFO in the form of fine zeolite residues ("cat fines") during catalytic cracking. With a particle-size distribution up to ca. 20 µm coupled with distinct oxidizing characteristics these materials are responsible for significant amounts of abrasive wear, especially in diesel motors. Nickel residues are converted by combustion into both water-soluble (nickel sulfite, nickel sulfate) and water-insoluble substances (nickel oxide, nickel carbonyl).

Limits with respect to the metals vanadium and aluminum have now been added to the norms for RFO. ISO 8217 specifies a maximum vanadium content of 150 – 600 mg/kg depending on the product classification, and a maximum aluminum content (regarded as an indicator of the level of cat fines) of 30 mg/kg.

Net and Gross Calorific Value Net calorific values of most residual fuels are in the range of 39.82 – 41.53 MJ/kg (11.06 – 11.54 kWh/kg). Systematic investigations by Marder have shown a direct relationship between the net calorific value of a petroleum fuel and its density and sulfur content. Net calorific values can be calculated with sufficient accuracy by the use of the following equations (modified Marder equations, neglecting the contribution of ash and based on anhydrous material):

$$\begin{aligned} \mathrm{LHV} &= 52.919 - 11.930 \times 10^{-3} \\ &\quad \times d^{15} - 0.293 \times \mathrm{S}\ (\mathrm{MJ/kg}) \\ &= 14.700 - 3.314 \times 10^{-3} \\ &\quad \times d^{15} - 0.081 \times \mathrm{S}\ (\mathrm{kWh/kg}) \end{aligned}$$

where d^{15} is the density at 15 °C (kg/m^3) and S is sulfur content (wt %)

Sediment Content. Sediments consist of inorganic or organic foreign matter remaining after extraction of RFO with boiling toluene (ISO 3735), *Sediment by Extraction*). Apart from inorganic materials, sediment arises through aging or from polymerization or condensation of various oil components. Sediment content is a subject of numerous standards; maximum observed values for RFO are ca. 0.25 wt %. Just like the asphaltenes, sediments can be the cause of filter clogging.

Water Content. RFO is essentially anhydrous when it leaves the refinery. Nevertheless, multiple transfers at sea and the formation of condensate during storage may result in product with a water content of 0.1 – 0.5 %. This can cause foaming and spattering when the material is heated above 100 °C and can also lead to burner problems.

2.5. Storage, Transportation, and Handling

From a legal standpoint and with respect to the risk of fire or water contamination, RFO is not a dangerous substance (flash point 70 –100 °C, ignition temperature > 220 °C, explosive limits in air 0.5 – 6.5 vol %). Thus, RFO can be stored in single-walled tanks with a capacity of 50 – 50 000 m^3 without special precautions (e.g., fire extinguishing equipment, protective dikes). For safety reasons the storage temperature should be

kept 10 – 15 °C below the flash point. Hydrogen sulfide may accumulate in the vapor space of an RFO storage tank, so vapor inhalation and skin contact should be avoided. Cleanup should be effected with ordinary cleansing agents; solvents should not be employed.

Water transport (ocean, inland waterways) may utilize bulk carrier or barge (500 – 1000 t); land transport is normally by railroad tank car (30 – 50 t) or tank truck (24 – 28 t). Transport temperature must be maintained high enough so that the maximum pumping viscosity of 600 –800 mm^2/s is not exceeded (e.g., at least 45 °C with a nominal viscosity at 100 °C of 50 mm^2/s). Unloading normally entails a centrifugal or screw-type pump, some RFO tank trucks are equipped to employ pressure supplied from exhaust gas either with or without an auxiliary compressor. On-site transfer generally involves either permanently installed pipelines or oil-tight hoses with appropriate couplings.

2.6. Environmental Protection

Residual fuel oil itself is not a source of environmental problems, but its combustion products are. The relationship between RFO components and air contamination contribution may be deduced from Table 7, which presents a schematic overview of the combustion process in the absence of flue gas treatment.

Table 7. Environmental consequences of fuel oil combustion

Starting materials	Reaction products	Product concentration in flue gas (based on 3 % O_2)
Metals, solid inorganic foreign matter (0.1 %)	ash	particulates, 50 – 200 mg/m^3
Carbon (ca. 87.5 %)	soot	particulates, 50 – 200 mg/m^3
Carbon – combustion air	CO	50 – 100 mg/m^3
Carbon – combustion air	CO_2	inert, though contributing to the "greenhouse effect"
Hydrogen – combustion air (ca. 10.6 %)	H_2O	inert, though contributing to the "greenhouse effect"
Nitrogen – combustion air (0.2 – 0.5 %)	95 % NO	
	5 % NO_2	NO_x; Σ 700 – 1100 mg/m^3
Sulfur – combustion air	97 % SO_2	
	3 % SO_3	SO_x; Σ 1700 – 8500 mg/m^3

Environmental considerations have led to worldwide efforts to enact legislation for drastically reducing the emission of harmful materials. The resulting emission limits can be met by consumers of large amounts of RFO only with the aid of flue gas treatment facilities, installation of which is proceeding rapidly. The most common secondary treatment measures at steam generating plants include:

1) Electrotatic precipitators (particulate removal)
2) Desulfurization plants (DESOX: wet gypsum method of SO_x removal)
3) Denitrification plants (DENOX: selected catalytic design for NO_x removal)

These secondary treatment methods may be supplemented by primary treatment directly at the burner. This is intended to minimize the formation of hazardous materials—especially CO and NO_x—directly at their source. Staged air/fuel combustion plays an important role in primary treatment, as does flue gas recycling ("low NO_x burners").

The EEC recommendation of November 24, 1988 sets the following limits with respect to liquid RFOs as a function of facility size:

SO_x = 500 – 1700 mg/m^3
Particulates = 50 mg/m^3
NO_x = 450 mg/m^3

Desulfurization is mandatory above 400 MW thermal output (new construction), EEC member states are expected to adopt these guidelines by July 1, 1990. The guidelines are intended to apply to existing as well as new facilities, and should assist the states in meeting their obligation to reduce total emissions. The United States, Japan, and the Scandinavian countries have adopted pollution control legislation in which targets are based upon local emission data

1. Introduction

CURTIUS published the first synthesis of hexamethylenediamine [*124-09-4*], 1,6-hexanediamine, 1,6-diaminohexane, $H_2N(CH_2)_6NH_2$, M_r 116.21, in 1900 [1]. The compound did not become important industrially until the late 1930s after the pioneering work at Du Pont on synthetic polymers [2]. One of these polymers was *nylon* (→ Polyamides), a polyamide produced from adipic acid [*124-04-9*] (→ Adipic Acid) and hexamethylenediamine. Du Pont subsequently began to produce hexamethylenediamine for manufacture of a synthetic fiber which they named nylon 66 (to distinguish it from nylon 6, a polyamide based on caprolactam). Nylon 66 rapidly gained acceptance for use in hosiery, lingerie, and other types of clothing, for military applications, and later for molded plastic parts. Du Pont was quickly joined by ICI in the production of nylon 66.

The commercial success of nylon led to expanded production of hexamethylenediamine in the postwar years, but it remained a captive product for nylon manufacture and was not generally for sale. This situation changed gradually, particularly after the development of light-stable polyurethanes based on aliphatic diisocyanates and the introduction by Bayer of a polyisocyanate (Desmodur N) made from hexamethylenediamine [3]. Hexamethylenediamine is now a commercial product available as an aqueous solution in several strengths, as anhydrous material in drums, or as a melt in insulated tank cars.

2. Physical Properties [4,5]

Hexamethylenediamine is a colorless solid with a typical fishlike amine odor. It is very soluble in water, soluble in alcohols and aromatic solvents, and poorly soluble in aliphatic hydrocarbons. The following shows its vapor pressure as a function of temperature [6]:

t, °C	200.6	181.2	154.3	135.1	117.7
p, kPa	101.3	60.0	26.7	13.3	6.7

Some physical properties are:

mp	41 °C
Density (25 °C)	0.854 g/cm^3
Flash point (open cup)	94 °C
Dissociation constant (water, 20 °C)	
pK_1	11.11
pK_2	10.01
Heat of combustion (25°C)	40 208 kJ/kg
Specific heat capacity, c_p (solid)	2.85 kJ kg^{-1} K^{-1}
mp of water eutectic (53 % H_2O)	− 20 °C
Solubility in 100 g water (30 °C)	960 g
Heat of solution in water, J/g	
90 % solution	56
85 % solution	71
70 % solution	112
Infinite dilution	245

Properties of an aqueous solution [7] are as follows:

	Concentration, wt %		
	90	85	70
mp, °C	30	24	6
bp, °C	129.5	122.3	111.5
Density (25 °C), g/cm^3	0.889	0.900	0.929
Flash point (open cup), °C	102	107	116

3. Chemical Properties

Hexamethylenediamine is a strong organic base, e.g., a 10 % aqueous solution has a pH of 12.3 (20 °C), and forms stable salts with both organic and inorganic acids. The most important salt is that produced by neutralization with adipic acid (salt strike): the so-called nylon salt or AH salt. This compound is the raw material for the preparation of nylon by thermal dehydration under vacuum.

Other reactions of hexamethylenediamine are typical of aliphatic amines (→ Amines, Aliphatic). The preparation of hexamethylene diisocyanate [*822-06-0*] by reaction with phosgene is industrially important:

$$H_2N(CH_2)_6NH_2 + 2\,COCl_2 \longrightarrow OCN(CH_2)_6NCO + 4\,HCl$$

The reaction takes place in a chlorinated aromatic solvent with a yield of 95 % or more [8]. Hexamethylene diisocyanate can also be produced by converting hexamethylenediamine to an aliphatic urethane, followed by thermal cleavage [9] (→ Isocyanates, Organic).

4. Production

Virtually all hexamethylenediamine is now produced by the *catalytic hydrogenation of adiponitrile* [*111-69-3*] (→ Adipic Acid, Chap. 8.1.):

$$NC(CH_2)_4CN + 4\,H_2 \longrightarrow H_2N(CH_2)_6NH_2$$

This process is carried out in the liquid phase in the presence of ammonia, which serves as a heat-transfer medium and which, with some catalysts, improves yields by decreasing the extent of side reactions [10, 11]. A variety of catalysts can be used, most of which are based on promoted (i.e., activated or doped) cobalt [12–15], but iron oxide is also effective [16, 17]. Typical reaction temperature is 100 – 200 °C, and operating pressure is usually high, e.g., 28 – 41 MPa. Purification is by distillation, with a yield of ca. 85 % [18]. Byproducts are 1,2-diaminocyclohexane [*694-83-7*], hexamethyleneimine [*111-49-9*], and bis(hexamethylenetriamine) [*143-23-7*], all of which are recovered for sale.

Adiponitrile itself is produced commercially by at least three processes, each based on a different hydrocarbon. The original process commercialized by Du Pont and still used in a number of adiponitrile plants starts with adipic acid made from cyclohexane:

$$C_6H_{12} \xrightarrow{\text{Air}} C_6H_{11}OH + C_6H_{10}O$$
$$C_6H_{11}OH + C_6H_{10}O + HNO_3 \longrightarrow HOOC(CH_2)_4COOH$$

Adipic acid reacts with ammonia at 300 – 400 °C and atmospheric pressure in the presence of a catalyst to give adiponitrile in yields as high as 95 % [19–21]:

$$HOOC(CH_2)_4COOH \xrightarrow{NH_3} NC(CH_2)_4CN$$

Du Pont abandoned this method after developing a process for the catalytic addition of hydrogen cyanide to butadiene [22, 23]:

$$CH_2{=}CHCH{=}CH_2 \xrightarrow{HCN} NC(CH_2)_4CN$$

This reaction is carried out at ca. 100 °C and sufficient pressure to maintain the reaction in the liquid phase. Adiponitrile is separated from byproducts by distillation.

A third route to adiponitrile is by electrolytic dimerization of acrylonitrile [*107-13-1*], produced by the ammoxidation of propene [*115-07-1*] [24]. This process, developed by Monsanto, was commercialized in 1965. The following reaction takes place at the cathode in an electrolytic cell:

$$2\,CH_2{=}CHCN + 2\,H^+ + 2\,e \longrightarrow NC(CH_2)_4CN$$

Hydrogen ions are formed from water at the anode and pass to the cathode through a membrane. The catholyte consists of a mixture of acrylonitrile, water, and a tetraalkylammonium salt. The anolyte is aqueous sulfuric acid. The yield of adiponitrile based on acrylonitrile is 92 – 95 %. Small amounts of propionitrile and bis(cyanoethyl) ether are formed as byproducts.

A direct route to hexamethylenediamine, not based on adiponitrile, was used by Celanese but discontinued in 1984: hydrogenation of adipic acid esters to 1,6-hexanediol [*629-11-8*],

which then reacted with ammonia at 219 °C and 22.8 MPa.

In Western Europe, hexamethylenediamine is made from adipic acid via adiponitrile by ICI, BASF, and Rhône-Poulenc; BASF also makes adiponitrile by electrolytic dimerization of acrylonitrile. Butachimie, a joint venture of Du Pont and Rhône-Poulenc, uses adiponitrile produced by the Du Pont hydrocyanation route. In Japan, the only hexamethylenediamine producer is Asahi Chemical, which uses electrolytic dimerization of acrylonitrile to manufacture the adiponitrile intermediate. Rhodia, the South American producer, also uses acrylonitrile as raw material.

5. Quality Specifications and Analysis

The color of aqueous hexamethylenediamine solutions and nylon salt solutions is considered an indication of purity. When these solutions are prepared from pure hexamethylenediamine, they are essentially water-white at first but slowly develop color on storage in contact with air. Solutions prepared from diamine containing impurities such as 1,2-diaminocyclohexane, hexamethyleneimine, and tetrahydroazepine develop color more rapidly, depending on the level of impurities and the storage temperature. The color of the polyamide produced is related to the color of the hexamethylenediamine and the nylon salt solution used.

Although no impurity specifications are given for commercial hexamethylenediamine, typical specifications for polymer-grade hexamethylenediamine (maximum content, parts per million) are

1,2-Diaminocyclohexane	50
6-Aminocapronitrile	10
2-Aminomethylcyclopentylamine	100
Hexamethyleneimine	25
Tetrahydroazepine	100
Ammonia	50
Color, Pt – Co scale (APHA)	10

1,2-Diaminocyclohexane and 2-aminomethylcyclopentylamine [*21544-02-5*] are determined by gas chromatography with a capillary column. Ammonia [*7664-41-7*], 6-aminocapronitrile [*2432-74-8*], and hexamethyleneimine are analyzed by a combination of distillation and titration. Ammonia is removed first by simple distillation with methanol as a carrier; the distillate is collected in boric acid solution and titrated with standard acid. After removal of ammonia, the sample is made alkaline with aqueous sodium hydroxide and refluxed to hydrolyze the aminocapronitrile to sodium aminocaproate. The ammonia liberated in this step is distilled with methanol and titrated with acid. The distillation is then continued into an aqueous fraction that carries over the hexamethyleneimine, which forms a binary azeotrope (*bp* 95.5 °C; 50.5 wt % imine) with water. This fraction is collected in neutral water and titrated with standard acid. Tetrahydroazepine can be determined by pulse polarography. Because azepine is a Schiff base, standards may be prepared by adding an aliphatic aldehyde to the hexamethylenediamine sample to give another Schiff base. The color is determined by a standard comparison colorimeter.

6. Storage and Transportation

Hexamethylenediamine should be stored in tightly closed containers in well-ventilated areas.

Shipping Information [5], [7].

United States, other than by air (DOT)

Shipping name	hexamethylenediamine, solid hexamethylenediamine, anhydrous hexamethylenediamine, solution
Hazard class	corrosive material
UN/NA no. (solid)	UN 2280
UN/NA no. (liquid)	UN 1783
DOT hazard classification	corrosive
Freight class	chemicals NOI

International, by water or air (IMO/ICA)

Hazard class	IMCO 8
UN no. (solid)	UN 2280
UN no. (liquid)	UN 1783
IMO/ICAO label(s) (solid)	corrosive
IMO/ICAO label(s) (solution)	corrosive/poison
Subsidiary risk	6.1
Packaging group	II

7. Economic Aspects

Hexamethylenediamine production capacities (thousand tonnes) in 1986 are given below:

Canada	45
United States	630
South America	13
Western Europe	331
Japan	30
People's Republic of China	21
	1071

The United States and Western Europe account for approximately 90 % of the estimated world capacity of hexamethylenediamine. Because more than 95 % of production is used for nylon 66 fibers and plastics, the future of hexamethylenediamine remains dependent on the growth of this particular nylon. Production of Hexamethylenediamine in 1995 is 658 x 10^3 t in the USA, 370 x 10^3 t in Western Europe, and 46 x 10^3 t in Japan [28].

8. Toxicology and Occupational Health

Exposure of humans to hexamethylenediamine by inhalation, ingestion, or skin or eye contact may cause eye irritation or blurring of vision, upper respiratory tract irritation, or skin irritation [25]. Higher exposures lead to abnormal liver function, skin burns, or eye corrosion with corneal or conjunctival ulceration. Skin sensitization has been reported in some individuals, and some evidence exists that hexamethylenediamine permeates the skin [26].

The following animal toxicities have been determined [5]: (ALC), LC_{50} 1580 ppm (mouse, inhalation, 10 min); LC_{50} 1100 mg/kg (rabbit, skin absorption); and LD_{50} 792 – 1127 mg/kg (rat, oral). Hexamethylenediamine is corrosive to the skin and eyes of animals but no evidence of skin sensitization exists. On exposure by inhalation, animals have exhibited upper and lower respiratory tract irritation [27]. Other reported effects on animals by ingestion, inhalation, and skin contact include weight loss and liver or kidney damage. The compound is not embryotoxic in animal tests. No mutagenic activity has been observed in bacterial and mammalian cell cultures.

1. Introduction

Heat – in the physical sense – is a form of energy and can be stored in various ways and for many different applications. *Low-temperature heat* is stored for domestic hot water supply, *high-temperature heat* for power processes; short-term and long-term storage can be applied in house heating; storage in stationary constructions has been experienced in ground stores or buildings, while storage in mobile equipment is commonly used in fuel for automotive engines. Each storage concept has its best suited materials and these may occur in different physical phases: as solids, liquids, or gases.

A special kind of heat storage media are fossil or nuclear fuels, such as wood, coal, oil, or uranium. These are characterized by a very high energy density (e.g., 42.7 MJ/kg in diesel oil) and an irreversible application. Since storage is understood in this article as a reversible process which can be repeated more or less indefinitely, the irreversible storage processes and their materials will not be treated here. The materials considered in what follows are characteristic for the storage of (1) sensible heat, (2) latent heat, and (3) chemical heat.

2. Practical Principles for Heat Storage Media

The following requirements should be met by heat storage materials:

1) Long service life, noncorrosive, nontoxic, nonflammable
2) Large heat storage capacity
3) Proper thermal diffusivity (temperature diffusivity) $a=\lambda/\varrho c\ \left[\mathrm{m^2/s}\right]$ and high heat diffusivity $b=\sqrt{\lambda\varrho c}\ \left[\mathrm{Jm^{-2}K^{-1}s^{-1/2}}\right]$ (where λ is the thermal conductivity, ϱ the density, and c the specific heat capacity
4) Ability to undergo charging – discharging cycles without loss in performance and storage capacity, or change in structure
5) Easy availability, simple in handling, and storable in simple containment
6) Inexpensiveness

A decisive criterion of a heat storage medium is its price and the costs that arise upon its utilization. Long life and a high cycling stability are prerequisites for economic application, i.e., at a price competitive with existing storage facilities. High thermal diffusivity of the heat storage material provides a quick response to temperature differences, i.e., quick charging and discharging; high heat diffusivity yields a high amount of heat being stored.

Heat transfer processes have to be considered: the heat may be either transferred directly to the storage material as, for example, in a dry pebble bed with air flow, or a heat exchanger may be required as in a solar domestic hot water store where the water – antifreeze mixture flowing through a solar collector has to be separated from the hot water for consumption. Other aspects of selecting a heat storage material may be

Solid – liquid combinations	liquid ↔ gas	adsorbents – adsorbates
Water-flooded pebbles	salt hydrates	
Oil – cast iron	eutectica	

operational advantages in energy supply systems or a larger flexibility in application. A survey of heat storage media is given in Table 1.

3. Storage of Sensible Heat

Sensible heat always results in an increase or decrease of the material temperature. All materials have a capability of absorbing and storing heat due to the fact that they have a mass m and a specific heat capacity c_{p} at constant pressure. For a temperature difference $\Delta T = T_2 - T_1$ this heat (or enthalpy) amounts to

$$Q_{\mathrm{sensible}} = m c_{\mathrm{p}} \, (T_2 - T_1) \tag{1}$$

where the unit of Q is, for example, J. T_2 denotes the material temperature at the end of the heat absorbing (charging) process and T_1 at the beginning of this process. This heat is released in the respective discharging process. For pure solids (especially heavy elements), the specific heat per mole of a substance is ca. $3R$ (Dulong – Petit rule), with R being the molar gas constant ($R = 8.31441$ J mol^{-1}K^{-1}). Thus, the molar thermal energy q_{mol} stored in solids can be approximated by

$$q_{\mathrm{mol}} \approx 3R \cdot \Delta T \tag{2}$$

and q_{mol} is measured in, for example, J/mol. Thus, approximately 25 J/mol can be stored with a temperature difference of $\Delta T = 1$ K. With the molar mass M (kg/mol), the thermal energy q stored per mass (storage capacity in J/kg) is obtained

$$q = c \Delta T = q_{\mathrm{mol}} / M = 3R \cdot \Delta T / M \tag{3}$$

In Table 2 some characteristic materials are listed together with their thermophysical properties.

The metals and graphite are best suited for quick charging and discharging (high thermal diffusivity a) and for a large amount of heat stored (high heat diffusivity b). Other solid materials such as stones are much less advantageous, their respective values are smaller by an order of magnitude. Liquids and gases – despite their inattractive thermophysical properties – offer the advantage of a possible use as both storage medium and heat carrier. The most widely applied media, in this respect, are water and air.

3.1. Solid Storage Materials

Solid materials can be heated to very high temperature (e.g., magnesia bricks in Cowper regenerators to 1000 °C). They are usually chemically inert and, in the form of rocks and pebbles, abundant and cheap.

Pebble bed and rock pile stores consist of loosely packed material in a container. Heat has to be carried to or from such stores by a heat carrier such as air or water. These beds provide a large surface area for heat transfer in their dispersed materials; the internal heat losses are only small because the particles have little surface contact to surrounding particles and thus, little conduction losses. Reduced insulation around the storage container is sufficient when air – with a small thermal conductivity – is used as a heat carrier and fills the gaps between the particles. Such particle beds, however, cause a large pressure drop in the fluid flow. This has to be compensated by pumps or compressors. Another drawback is the large storage volume required. Conveniently, this is provided in underground installations.

In ground stores, heat is stored in soil, stones, or solid rocks, especially for low-temperature storage. *Cast iron* is an inexpensive material with a high volumetric heat capacity (energy density) $q \cdot \varrho$. It is used for high-temperature storage together with oil as the heat carrier. As solid materials for storage always have to be combined with fluid heat carriers, properties of the solids have to be taken into account which affect fluid flow and heat transfer, e.g., particle and container size, mechanical durability against abrasion and thermal cycling, hygroscopy, etc. In Figure 1, a storage bin for solid materials with gas as a heat carrier is shown. If the packing density is high, e.g., for small solid particles, the storage capacity is high, but the pressure drop is also high. A proper particle size which should be rather uniform has to be found.

The thermal stratification (see Section 3.2) is well maintained in a solid-material heat store, because natural convection in the heat carrier is suppressed by the granulate and internal heat conduction is low, because of the aforementioned reasons. Containers as shown in Figure 1– in form of pillars – are used as architectural components in buildings. The combination of hollow bricks and air has been known as hypocaust-heating systems since antiquity. Water-flooded pebble beds are known as artificial aquifers.

Figure 1. Storage bin for solid materials
a) Air-distribution chamber; b) Grating; c) Rocks; d) Insulation

3.2. Liquid Storage Materials

Water. The most widely used liquid for thermal storage is water. Water has the following advantages:

1) It is abundant and inexpensive
2) It has a relatively high heat diffusivity ($b = 1.58 \times 10^3\ \mathrm{Jm^{-2}\,K^{-1}s^{-1/2}}$)
3) A relatively low thermal (temperature) diffusivity ($a = 0.142 \times 10^{-6}\ \mathrm{m^2/s}$); an advantage for thermal stratification within a hot-water storage tank
4) It can be easily stored in all kinds of containers
5) The control of water flow systems is highly flexible and is often state-of-the-art
6) Water can be used without heat exchangers
7) Is is easy to handle, nontoxic, noncombustible, experience with water is common
8) It is easily mixable with additives (antifreeze, anticorrosive)

Thermal stratification in heat storage vessels is desired, because the value of high temperature heat is maintained in the upper part of the vessel, while low-temperature fluid (as backflow from a heat consumer) can still be stored in the lower part of the vessel. The temperature distribution within a storage vessel is shown in Figure 2 for various lengths of time. Due to transient internal heat conduction, the stratification is destroyed in the course of time, even in very well insulated vessels (time 3 represents a longer time duration than time 1).

Water has the following disadvantages:

1) It only provides a limited operation range between 0 °C (freezing) and 100 °C (boiling)
2) It is corrosive
3) It has high vapor pressures ($p > 5$ bar) at temperatures > 155 °C

The vapor pressure can be reduced when mixtures of water with other chemicals are applied; e.g., a mixture of 50 % H_2O and 50 % NaOH can be used up to 140 °C without a pressure vessel.

Other Liquid Storage Materials. Other liquids, oils, molten salts, and metals (Na) are used for high-temperature storage as their vapor pressures are low. Freezing points of such materials, however, have to be taken into consideration (e.g., for Na $\theta_m = 98$ °C). Oils and paraffins may be used as heat carriers in combination with solids.

Figure 2. Thermal stratification in a hot-water storage vessel (warm water zone, gradient zone, and mixing are valid for time 1)

Applications Storage tanks for hot water are used in industry and dwellings. They come in sizes of 0.1 m^3 (domestic hot water storage) to 12 000 m^3 (solar assisted district heating). The most recent development are "solar combination stores" of about 0.5 m^3 which serve for both domestic hot water supply and house heating. In Figure 3 such a metal storage tank is shown with its heat exchangers for a good thermal stratification.

Water is commonly used also in large thermal stores, both as storage medium and heat transfer fluid. In large stores (e.g., seasonal stores for solar energy) the storage capacity can be turned over only once or – at the most – three times a year. Such a small energy turnover makes the stored heat expensive unless the storage container is inexpensive. A rough comparison of energy cost for various storage concepts is given in Table 3. Here, "energy cost" is the cost per kilowatt-hour. The energy considered is the heat stored in one annular cycle. The cost is based on investments for a 15 years' payoff time and 6 % interest.

Figure 3. Solar combination storeS_{in} = Solar loop from collector; S_{out} = Solar loop to collector; A_{in} = Auxiliary heating loop inlet; A_{out} = Auxiliary heating loop outlet; SH_{in} = Space heating loop inlet; SH_{out} = Space heating loop outlet; CW = cold water inlet; HW = Hot water outlet; T = Temperature sensor

Table 3. Energy cost for various storage concepts

	Cost, DM/kWh	Volume, m^3	Max. temp., °C	Max. efficency, %
Steel tank	0.044 – 0.078	10 000	85	78
Ground container	0.030 – 0.070	15 000	85	80
Rock cavern	0.021 – 0.050	105 000	75	85
Rock boreholes	0.009 – 0.027	11 000	50	85
Ground boreholes	0.009 – 0.034	30 000	50	50
Aquifer	0.003 – 0.026	800 000	35	80

A technical/economical boundary for *steel tanks* is a size of around 100 000 m^3. For *ground containers,* the waterproof liner may create problems (e.g., tightness after welding, perforation by stones): plastic- and stainless steel-liners are used. These large containers are built of concrete and they are fully or partly buried in the ground. Their capacity is around 80 kWh/m^3. A schematic view of such a container is shown in Figure 4. In summer, hot water is fed to the water layers on top and cold water withdrawn from the bottom, in winter, hot water is withdrawn from the top layers and cold water re-fed at the bottom.

In so-called *ground stores* low temperature heat is stored in soil or pebbles. The storage medium in such cases is a mixture of water and solid particles. Density ϱ and specific heat capacity c of these mixtures can be obtained from the mixing laws. The thermal conductivity λ depends strongly on the composition of the mixture. Although some mathematical equations exist in the literature, reliable data for λ depend on measurements. Heat is usually exchanged with the ground by tubes containing a circulating carrier fluid, mostly water. These tubes may be placed close to the surface (0.5 – 1 m below) in a meandering arrangement or spirally wound in horizontal ditches. For large stores (more than 10 000 m^3 water equivalent storage capacity), vertical holes are drilled for the heat exchanger tubes (see Fig. 5, next page).

In some areas, geology allows for a so-called *aquifer store.* This requires a permeable layer of soil (pebbles or sand) enclosed between horizontal layers of impermeable material (clay). Under such advantageous conditions, two fountains can be drilled some distance apart from each other and hot water can be inserted in summer and withdrawn in winter (see Fig. 6). Prob-

Figure 4. Schematic view of a large hot water storage vessel

lems can arise from minerals dissolving in the water and precipitating on tubes and heat exchangers.

So-called *man-made aquifers* are built in sizes of 10 000 m^3; the ground excavations are filled with pebbles and water and sealed by plastic sheets [14]. In all cases where mixtures of water and solid material are used for heat storage, the storage volume has to be larger than in the case of pure water. Rough data are given in Table 4.

Figure 5. Schematic view of a borehole heat store

Table 4. Storage volume of different storage media compared to pure water for 1 m^3 water equivalent and 60 kWh capacity at $\Delta T = 50$ K

Storage media	Storage volume
Hot water storage	1 m^3
Pebble – water storage	1.3 – 2 m^3
Aquifer storage	2 – 3 m^3
Borehole storage	4 – 5 m^3

3.3. Gaseous Storage Materials

Gases have extremely low heat diffusivities and are particularly unsuitable for *storing heat.* Moreover, their volumetric specific heat capacity $\varrho\ c_p$ is extremely low (ca. 1 $kJm^{-3}\,K^{-1}$) while that of solids or liquids is between 1000 and 4200 $kJm^{-3}\,K^{-1}$ (e.g., for water $\varrho\ c_p = 4200\ kJm^{-3}\,K^{-1}$).

Gases are, however, highly important *heat carriers,* especially at elevated and very high temperature. *Air* and *flue-gases* are the heat carriers in Cowper regenerators. *Air* is used as a quickly responding carrier with little thermal inertia in air heating systems with pebble-bed storage. *Hydrogen* is stored in metal hydrides either as a later fuel or as a reactant for chemical heat storage. *Water vapor* is created when the pressure from a steam accumulator (Ruths store) is released. Ruths stores are used in peak-load storage plants of power stations or for process heat in industries of chemical, food, and metallurgical branches. The heat is actually stored in the saturated steam or pressurized water. Gases require large volumes or pressure vessels for storage.

4. Storage of Latent Heat [6–12]

Materials for the storage of latent heat are also named *phase change materials* (PCM), because of the fact that they change their physical phase

Figure 6. Schematic view of an aquifer heat store

from solid to liquid or liquid to gas and vice versa. The phase change is always coupled with the absorption of heat when the solid melts and the liquid evaporates – heat of melting or heat of evaporation – and a heat release when the liquid solidifies or the gas condenses. The phase change occurs at the melting or evaporation temperature T_{m} or T_v. At that temperature, these materials melt or evaporate when heat is added, but do not exhibit a rise in temperature. Thus, the heat added cannot be sensed and appears to be latent.

A change of one crystalline form into another without a physical phase change may also be considered as storage of latent heat. The phase change of salt hydrates is considered a solid – liquid transformation. The solid hydrate crystals release their water of crystallization at a certain temperature (or a temperature range) and the anhydrous salt dissolves in this water. This process is reversed when heat is withdrawn. The heat (or enthalpy at p = const.) stored with a phase change amounts to

$$q_{\mathrm{latent}} = \Delta h_{\mathrm{m}} \text{ or } \Delta h_{\mathrm{v}} \tag{4}$$

where Δh_{m} is the latent heat (enthalpy) of melting and Δh_{v} the latent heat (enthalpy) of evaporization.

When a material is heated from an initial temperature T_1 to the melting temperature T_{m} and the melt is further heated to T_2, the total heat stored is

$$Q_{\mathrm{total}} = Q_{\mathrm{sensible,solid}} + Q_{\mathrm{latent}} + Q_{\mathrm{sensible,liquid}} \quad q_{\mathrm{total}} \cdot m \tag{5}$$

or using Equations (1) and (4):

$$Q_{\mathrm{total}} = m \cdot c_{\mathrm{solid}} (T_{\mathrm{m}} - T_1) + m \Delta h_{\mathrm{m}} + m \cdot c_{\mathrm{liquid}} (T_2 - T_{\mathrm{m}}) \tag{6}$$

The specific heat capacity of the solid phase is c_{solid} and of the liquid phase c_{liquid}.

For a *liquid – gaseous phase change*, the total heat stored is accordingly

$$Q_{\mathrm{total}} = m \cdot c_{\mathrm{liquid}} (T_{\mathrm{v}} - T_1) + m \Delta h_{\mathrm{v}} + m \cdot c_{p\mathrm{gas}} (T_2 - T_{\mathrm{v}}) \tag{7}$$

with T_{v} as the temperature of evaporation. The heat of fusion (i.e., the heat of melting or evaporation) is much greater than the sensible heat. Therefore, phase change materials have a larger volumetric energy storage capacity than sensible storage materials. A further advantage of PCMs is the absorption and the release of heat at a constant temperature; this melting or evaporation temperature is material-specific and the material can be selected accordingly.

A rough estimate of the heat of fusion of the various phase change materials can be obtained from the following formulas. For most pure metals, the *molar heat of melting* $\Delta h_{\mathrm{m,\,mol}}$ is within the range (T_{m} in K)

$$RT_{\mathrm{m}} < \Delta h_{\mathrm{m,mol}} < 1.5RT_{\mathrm{m}} \tag{8}$$

For semiconductors, eutectic, and inorganic compounds, the range is

$$2.5RT_{\mathrm{m}} < \Delta h_{\mathrm{m,mol}} < 5RT_{\mathrm{m}} \tag{9}$$

The following approximation can be used for organic substances

$$\Delta h_{\mathrm{m}} \approx 24T_{\mathrm{m}}/M \tag{10}$$

giving Δh_{m} in J/g for the molar mass M in g/mol.

The *latent heat of evaporation* can roughly be approximated (at 1 bar) by Trouton's rule

$$\Delta h_{\mathrm{v,mol}} \approx 9T_{\mathrm{v}}R \tag{11}$$

Comparison with data in literature, however, indicates a range of

$$6RT_{\mathrm{v}} < \Delta h_{\mathrm{v,mol}} < 15RT_{\mathrm{v}} \tag{12}$$

Latent heat storage materials should be inexpensive and be characterized by

1) A large phase-change enthalpy and a high density
2) A large thermal diffusivity in the solid and liquid phase
3) Thermal stability and cycle stability
4) Little or no subcooling during freezing and little or no supersaturation during melting
5) A low thermal expansion, i.e., low volume change during melting

They should neither exhibit segregation (e.g., like Glauber's salt), nor be corrosive, or react with casing materials, should not be poisonous, inflammable, or form explosive phases.

Various phase change materials are listed together with their thermophysical properties in Tables 5 and 6.

Thermophysical properties are not always available and their values may differ in literature. Impurities in the substances can change the properties considerably. The tables only present characteristic materials, many more are found in literature. For heat storage in the low-temperature range (<50 °C; e.g., for solar energy) salt hydrates and paraffins are mainly considered.

4.1. Salt Hydrates

Many salt hydrates are sufficiently inexpensive; they are only little corrosive and slightly toxic. They exhibit only small changes in volume during phase change and have a relatively high heat of fusion (compared to organic compounds) at low melting temperature. Salt hydrates are of the chemical form $X(Y)_i \cdot n\,H_2O$ with $X(Y)_i$ representing an inorganic compound. When the salt hydrate is heated to its transition temperature, one of the following reactions will take place

$$X(Y)_i \cdot n\,H_2O \longrightarrow X(Y)_i + n\,H_2O \quad (13)$$

$$X(Y)_i \cdot n\,H_2O \longrightarrow X(Y)_i \cdot o\,H_2O + (n-o)\,H_2O) \quad (14)$$

At the melting point, the hydrate crystals split up into either an anhydrous salt and water (13) or into a hydrate with a lower number of water molecules and water (14).

Salt hydrates have two drawbacks for thermal storage: they suffer from incongruent melting and supercooling.

Incongruent melting occurs when not enough water of crystallization is released during thawing and the anhydrous salt cannot completely dissolve. The solid residual part settles at the bottom of the container due to its higher density. In the reverse process (during recrystallization) some fraction of the precipitated solid is unable to come into contact with the water necessary for its recrystallization. Thus, the useful heat of fusion reduces after several charge – discharge cycles. Incongruent melting can be prevented by:

1) Addition of a thickening agent which holds the anhydrous solid part in suspension and prevents its settling
2) Stirring, vibrating, or rotating the material
3) Addition of excess water
4) Encapsulation of the material (e.g., in plastics, as metallic containers may be corroded)

Supercooling occurs during cooling (heat discharge) when no sufficient nucleation sites are available. The crystallization does not take place at the melting point; the liquid is cooled below that point and the stored heat is not discharged at the expected melting temperature, but at some arbitrary temperature. In some cases it might happen that the stored heat cannot be withdrawn, because the temperature difference between the subcooled melt and the required load temperature, is not high enough.

One of the following means can promote the initial crystallization and prevent supercooling:

1) Addition of small quantities of a nucleating agent with a crystal structure similar to that of the salt
2) Use of a container with rough walls (the peaks and pins form nucleation sites)
3) Preservation of a "cold spot" in the container, where no melting takes place and crystals survive

If the rate of crystal growth is high and there is good heat transfer from the walls, then the temperature of the supercooled melt can quickly rise to the melting point and is maintained for the recrystallization process. In this case, subcooling may be tolerated.

4.2. Paraffins

Paraffins are waxy solids at room temperature. Their melting points and heat of fusion increase with molar mass. Compounds in the series $C_{14}H_{30} - C_{40}H_{82}$ have melting points in the range 6 – 80 °C. They are advantageous storage materials for the following reasons:

1) They are widely available and inexpensive
2) Noncorrosive and nontoxic
3) Chemically stable, with a low density
4) Phase transformation is rapid
5) Supercooling is negligible

But they show the following drawbacks:

1) Low volumetric energy density (compared to salt hydrates)
2) Change in volume during melting by 10 %
3) Low thermal conductivity and diffusivity
4) No distinct melting point, because cheap technical paraffins used for thermal storage are mixtures of many compounds
5) Not compatible with plastics

5. Storage of Chemical Heat [12, 13]

Reversible thermochemical reactions can be used for storing thermal energy. The energy is stored in the form of chemical compounds created by an endothermic reaction and it is recovered again by recombining the compounds in an exothermic reaction. The heat stored and released is equivalent to the heat (enthalpy) of reaction.

The enthalpy of reaction, generally, is much larger than the enthalpy of transition (in latent heat storage) or the sensible heat stored over a reasonable temperature span. The storage density (based on solid mass or volume) is much larger for thermochemical storage materials than for latent or sensible heat storage materials.

For thermochemical processes, the molar heat of reaction $\Delta h_{\mathrm{mol,\,r}}$ (at 1 bar) is approximately within the range

$$11RT_{\mathrm{r}} < \Delta h_{\mathrm{mol,r,gas}} < 19RT_{\mathrm{r}} \tag{15}$$

where T_{r} is the reaction temperature in K. The

specific heat of reaction (in J/g) can be roughly calculated from

$$\Delta h_{\mathrm{r}} \approx (100 - 150)\, T_{\mathrm{r}}/M \tag{16}$$

where M denotes the molar mass in g/mol. Materials for the storage of chemical heat, their temperature of reaction, and heat of reaction are given in Table 7.

The reversible reactions suitable for heat storage can be classified into thermal dissociation reactions and catalytic reactions.

Dissociation Reactions. Certain solid or liquid compounds can undergo dissociation reactions when they are heated. A gas is released while the depleted solid or liquid remains in the reactor (endothermic reaction, i.e., *charging of the store*). The reverse reaction will occur spontaneously if the equilibrium is changed by a temperature decrease or a pressure increase. Therefore, the dissociation products have to be separated and stored individually. For *discharge*, in the exothermic reaction, the gas is recombined with the solid or liquid. The reactions follow the scheme:

$$\mathrm{AB\ (solid\ or\ liquid)} \pm \mathrm{heat} \rightleftarrows \mathrm{C\ (solid\ or\ liquid)} + \mathrm{D\ (gas)}$$

A characteristic example is the dissociation of $Ca(OH)_2$:

$$Ca(OH)_2 \rightleftarrows CaO + H_2O$$

The respective storage arrangement is shown in Figure 7, see next page. The $Ca(OH)_2$ container serves as both the reactor and the CaO store. The water vapor evolved in the charging reaction is condensed and stored as liquid. For the discharge reaction, the liquid water is evaporated and returned to the CaO store where $Ca(OH)_2$ is formed again.

Catalytic Reactions. These are usually gas – gas reactions. A catalyst is required to obtain high reaction rates. The reaction products are transported in a pipeline from the charging source to the consumer (discharging sink). This system is called chemical heat pipeline or chemical heat pipe. The reactions follow the schemes

$$\mathrm{A\ (gas)} + \mathrm{B\ (gas)} \pm \mathrm{heat} \rightleftarrows \mathrm{C\ (gas)} + \mathrm{D\ (gas)}$$

Figure 7. Thermochemical energy storage using the reaction $Ca(OH)_2 \rightleftharpoons CaO + 2\,H_2O$
a) Condenser; b) Water store; c) Evaporator; d) $Ca(OH)_2$ reactor, CaO store

or

$$A\,(gas) \pm heat \rightleftarrows C\,(gas) + D\,(gas)$$

A characteristic example is the reaction:

$$CH_4 + H_2O \rightleftarrows CO + 3\,H_2$$

(Adam – Eva system, Jülich, Germany; see → Gas Production). The pipeline system is shown schematically in Figure 8.

Figure 8. Thermochemical pipeline

In thermochemical heat storage, the chemical compounds and the reaction products can be stored at ambient temperature for infinite time without heat losses. Thus, a thermal insulation of the storage containers is not required. The chemicals, however, have to be heated and cooled before reactions. This must be utilized in a carefully designed heat exchange equipment, in order to maintain a high overall system efficiency for the operational cycle.

In selecting the proper chemical materials, the following criteria have to be considered.

Reversibility. The reaction must go to completion, no side reactions or changes in reaction rate with time should occur.

Reaction Rates. Both forward and reverse reactions must be rapid enough to absorb all the available energy or release it promptly. The reaction rates must not decrease with cycling. Such a decrease is observed with the crushing of particles into powder when high heating rates and high temperatures are applied.

Controllability. The reactions must be controllable because they have to be turned on and off when required. Controllability is achieved by product separation, by control of temperature and pressure, or by catalysts.

Ease of Storage. This affects the cost considerably. The reaction products have to be easily separable prior to storage. Reactions must not occur at storage temperature.

Safety. Toxicity, inflammability, and corrosiveness of the reaction products may pose unacceptable safety hazards.

Cost. Cost should be low; this requires materials which are readily available.

For catalytic reactions the products need not be separated before storage which reduces the cost. In dissociation processes, when the reaction product is in a gaseous phase, separation is easy, but storage poses problems. The gas requires large storage volumes and the volumetric energy storage density is small: e.g., at 1 bar in the range of 0.5 to 1 kWh/m^3. When the gas is compressed, expensive pressure vessels and extra electrical energy for the compressor are needed. Various possibilities of reactions and storage are shown in Figure 9. The gas can be *condensed* and stored as a liquid in a small volume (Fig. 9B). Vapor of water and methanol can easily be condensed. For gases such as SO_2 and NH_3 this is more difficult and the liquification of H_2 requires a considerable amount of extra energy. A disadvantage of liquid storage is that the condensed phase has to be again evaporated for

the reverse reaction. This latent heat of evaporation must be considered a thermal loss, unless it is utilized in the condensation process. When the latent heat is not used, the obtainable thermal efficiency will be less than 50 %. Under favorable conditions (depending on the pressure – temperature relation), the evaporation occurs within the ambient temperature level. Such arrangements are utilized in intermittently working absorption refrigerators.

The gaseous product of a primary reaction can also be *absorbed* by another chemical in a secondary reaction (Fig. 9C). The secondary-store absorbent should be capable of absorbing the gas near ambient temperature. When energy is required, some heat is supplied to the secondary-storage container, the gas is released, and flows back to the primary-storage container. Here high-temperature heat is produced in a reversible reaction (thermochemical transformer, chemical heat pump).

An interesting arrangement of a *thermochemical power plant* is shown in Figure 9D. The exhaust steam of a turbine reacts in the store with some chemical (e.g., NaOH) exothermally. Water vapor is created within the store by the heat released and this vapor is used for the operation of the turbine. Recharging of the store may be accomplished by heating the chemical from a high-temperature heat source and returning the desorbed and condensed water vapor to a boiler reservoir. This principle was applied in the "Honigmann locomotive" (1882) with steam of 5.5 bar; the NaOH concentration was reduced from 82 % to ca. 65 %.

5.1. Thermochemical Transformer and Chemical Heat Pump

The pressure – temperature interrelation of such processes can be obtained from the equilibrium equation

$$\ln p = -(\Delta h_{\mathrm{r}}/\mathrm{R}) \cdot 1/T + \Delta s/R \qquad (17)$$

Figure 9. Various concepts for heat storage in dissociation processes
A) Gas storage; B) Compression of gas and subsequent liquid storage; C) Absorption in secondary reaction; D) Thermochemical power plant a) Absorbent; b) Gas store; c) Condenser, d) Liquid store; e) Evaporator; f) Secondary-store absorbent ▷ = charge; ▶ = discharge

where Δh_r is the (specific) heat of reaction, R the molar gas constant, and Δs the change of (specific) entropy due to the reaction. With Δh_r and Δs being considered constant over the temperature range used, the value of $\ln p$ depends linearly on $1/T$ and this dependence is plotted to provide necessary information on the required states of materials. The cycle of a *thermochemical transformer* is presented in Figure 10.

Figure 10. Pressure – temperature interrelation for a metal hydride heat transformer cycle

Two metal compounds are used which form hydrides according to the scheme

$$\text{Metal } nH_2 \pm \text{heat} \rightleftarrows \text{Metal } oH_2 + (n-o)H_2$$

with $o < n$ or $o = 0$.

The two compounds, $LaNi_{4.7}Al_{0.3}$, as the primary substance and $LaNi_5$ as the secondary one, are stored in two containers as in Figure 9C. Heat q is added to the hydride of $LaNi_{4.7}Al_{0.3}$ at 65 °C (1), hydrogen is released at a pressure of about 2.4 bar and absorbed in the second vessel by $LaNi_5$ at 26 °C (2) and a somewhat lower pressure. Low-temperature heat of reaction Δh_{r_2} has to be dissipated to the surroundings. For mere heat storage, the secondary store would be heated to 26 °C, in order to release hydrogen back to the primary store, where the heat of reaction is obtained at a higher temperature than 26 °C [the direction (1) to (2) is reversed, but with a pressure drop from (2) to (1)]. For transformer operation, however, the secondary store is heated up to 65 °C and 7.8 bar (3). At that state, hydrogen is released from the secondary store and reabsorbed in the primary store with an exothermic reaction which provides heat of reaction at 100 °C and 7 bar (4). When the heat delivered from the store reaches 65 °C (1), the cycle is closed, the store is discharged. The counterclockwise transformer cycle becomes a *chemical heat pump cycle* when the direction of the process is reversed (into a clockwise cycle, i.e., arrow directions being reversed). In this case, the flow of gas requires $p_4 > p_3$ and $p_2 > p_1$. The *transformer process* yields heat of a higher temperature than the heat delivered to the cycle, with a conversion efficiency (upgraded heat to delivered heat) of 0.5 to 1. The *heat pump process* utilizes heat of high temperature and of low temperature to provide heat of an intermediate temperature. Usually, the low-temperature heat input (at ambient temperature) is neglected. The conversion efficiency (provided heat to delivered heat) is in the range of 1 to 2.

Temperature levels required for such cycles depend on the compounds and the conversion efficiencies. The reactions are either of the liquid – gas (wet) or solid – gas type (dry). *Liquid – gas processes*, e.g., ammonia – water, water – lithium bromide, sulfuric acid – water are in use in absorption refrigerators and absorption heat pumps. They operate at varying input and output temperature, since concentration, besides pressure, affects the reaction. Heat and mass transfer problems are usually less than with solid – gas processes. *Solid – gas processes* have high rates of reaction which allow for compact devices; they operate at constant output temperature. Their drawback is a poor heat and mass transfer behavior, with low thermal diffusivity and high contact resistance. Solid materials exhibit sagging, swelling, and decomposition in long-term cycling. Side reactions may occur.

5.2. Adsorption Processes

Adsorption of a gas (adsorbate) on the surface of a solid (adsorbent) is a spontaneous exothermic process. By heating the solid, the gas is desorbed. This provides a means of storing heat: the absorption material is being charged when the gas is desorbed by heating (the adsorbent is free of gas), and discharged when the gas is adsorbed (the adsorbent becomes saturated with gas). The energy evolved during the process is the heat of adsorption.

A high heat-storage density can be achieved when a large amount of gas is adsorbed, and the heat of adsorption is large. A large quantity of gas can be adsorbed on a large surface: good adsorbents are porous solids with a very large internal surface area, originating from pore sizes of ca. 3 – 500 pm. The adsorbance rate is large when the temperature is low (below the equilibrium temperature). The heat of adsorption increases with the polarity of the adsorbate molecules; H_2O, NH_3, and CO_2 are suitable compounds. Water proves to be the best, because of its high dipole moment and latent heat. An adsorbent – water pair would not require a store for water. Since water vapor is readily available in the air, such a system could work in an open cycle.

Adsorbent materials have to be easily available and cheap. They should be chemically inert and should not undergo side reactions. Hygroscopic materials are proper adsorbents for water and widely used in industry. A number of such materials are listed with their relevant properties in Table 8

5.3. Effective Properties

Sorption processes are either exo- or endothermic. In either case, heat has to be transported within the storage material. In order to provide a large surface area for reaction in solid – gas processes, the storage material is in granular or powdery form. In such material, heat is transported simultaneously by conduction, convection, and radiation. These transport regimes cannot be separated, therefore effective properties such as effective thermal conductivity λ_{eff} and effective thermal diffusivity a_{eff} have to be measured so that layout calculations can be performed. Powdery materials of any kind, metal or ceramic, are very poor thermal conductors; especially when they are evacuated, they are often used as good insulators.

The *effective thermal conductivity* of the aforementioned $LaNi_{4.7}Al_{0.3}$ is shown as a function of pressure for various filling gases in Figure 11 [15]. The S-shaped curves are characteristic for powdery materials. The effective thermal conductivities differ according to the thermal conductivities of the filling gas λ_{gas}. The effect of the solid material can be observed by the fact that λ_{eff} is about 10 times higher than λ_{gas}. But, on the other hand, the thermal conductivity of solid $LaNi_{4.7}Al_{0.3}$ would be another ten times higher ($\lambda_{\mathrm{solid}} = 12.5\ \mathrm{Wm^{-1}\,K^{-1}}$). At high Knudsen numbers (i.e., mean free path/characteristic length) $Kn \geq 10$, at pressures below 10^{-4} bar, in the region of free molecular flow, when molecules move without collisions across the pores, the effective thermal conductivity is only about $0.004\ \mathrm{Wm^{-1}\,K^{-1}}$. This value is roughly independent of pressure and filling gas. Here, heat is transported by heat conduction in the grid.

Table 8. Thermophysical properties of adsorbent – adsorbate pairs

13 X	0.20	2400	480	0.92	600

Figure 11. Effective thermal conductivity of $LaNi_{4.7}Al_{0.3}$ (ψ_0 initial porosity, d_p initial particle diameter)

A similar, roughly S-shaped, distribution is obtained for the *effective thermal diffusivity.* In Figure 12 this diffusivity is shown for a zeolite and various filling gases [16].

Figure 12. Effective thermal diffusivity of zeolite NaA

The temperature effect on λ_{eff} is linear with about 2.2×10^{-3} K^{-1}. These low effective properties of sorbent materials are a drawback for their technical application; for the improvement a well conducting matrix (Al or Cu) is inserted into the storage material.

6. Summary

A comprehensive presentation of heat storage materials and their volumetric energy density is given in Figure 13 (see next page).

1. Definition and Classification

Although a strict definition of high-performance fibers does not yet exist, the term generally denotes fibers that give higher values in use in a range of applications. It commonly refers to fibers with some unique characteristics that differentiate them from commodity fibers such as nylon, polyester, and acrylic fibers. Synonyms are *specialty fibers* and, in some cases, *high-functional fibers.* High-performance fibers can be classified broadly into three categories according to their applications:

1) heat-resistant fibers, including flame-retardant ones;
2) high-modulus and high-strength fibers; and
3) other fibers

Tractable or fusible polymers can be spun from a polymer melt (*melt spinning*). Polymers that can be dissolved in a suitable solvent can be spun from a solution (*solution spinning*). The dissolved polymer is spun into a hot gas where the solvent evaporates (*dry spinning*) or into a liquid coagulating bath (*wet spinning*) (→ Fibers, 3. General Production Technology).

The concept of high-performance fibers covers not only organic but also inorganic fibers of carbon, alumina, and boron, which often include various whiskers (→ Fibers, 5. Synthetic Inorganic; → Whiskers). A variety of high-performance fibers can be found in composite materials (→ Composite Materials). Moreover, highmodulus fibers from aliphatic polymers, such as polyethylene or polyoxymethylene, also belong to the class of high-performance fibers

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a13_001

(→ Fibers, 4. Synthetic Organic, Chap. 4.). The classification of high-performance fibers is summarized in Figure 1.

Figure 1. Classification of high-performance fibers

The term high performance may also be applied to other properties such as radiation resistance [11], [12] or electrical conductivity [13] (→ Polymers, Electrically Conducting), but a discussion of these fibers is beyond the scope of this article. Here, discussion is restricted to the polymerization, fiber production, properties, and applications of fibers obtained from wholly aromatic polymers.

Table 1. Aromatic residues of meta- and para-oriented aromatic polymers [14]

Polymer	Aromatic residues
Meta-oriented	 3,3′-, 3,4′-, or 4,4′, X = CH_2, O, SO_2, S
Para-oriented	
Wholly aromatic polymers may be classified as *meta-* or *para-oriented,* depending on their chemical structure and properties. Fibers from meta-oriented polymers are useful as heat-resistant fibers. Para-oriented polymers are expected to be useful not only as heat-resistant fibers but also as high-strength (HS) or high-tenacity and high-modulus (HM) fibers. Typical examples of aromatic residues of the two classes are given in Table 1 [14].

Figure 2 shows the melting (softening) points of aromatic polyamides (aramids) with four components having *m-* or *p*-phenylene residues [15–18]. These four components are poly(*m*-phenyleneisophthalamide [*24938-60-1*] (PMIA),

poly(*m*-phenyleneterephthalamide) [*24938-63-4*] (PMTA),

poly(*p*-phenyleneisophthalamide) [*24938-61-2*] (PPIA), and

poly(*p*-phenyleneterephthalamide) [*24938-64-5*] (PPTA).

Fibers from PMIA, PMTA, or PPIA are heat-resistant and are classified in this article as meta-oriented according to their fiber properties.

Meta-oriented aramid fibers have a higher heat resistance than commodity fibers such as polyester or polyacrylonitrile fibers, as well as favorable physical and mechanical properties for clothing or textile use. The PMTA fibers have a higher heat resistance than PMIA fibers, but their physical and mechanical properties are similar; thus, they are defined as meta-oriented.

Heat-resistant, high-modulus PPTA fibers are defined as para-oriented. Some ambiguities inevitably arise in copolymers containing more than 50 mol % of para-substituted residues. Among the aramids shown in Figure 2, optical anisotropy in concentrated sulfuric acid is shown by polymers in which more than ca. 75 mol % of

the total phenylene residues are para-oriented. Such polymers can give high-modulus fibers [18].

Figure 2. Melting points (°C) of aramids [16]
PMIA = poly(*m*-phenyleneisophthalamide);
PMTA = poly(*m*-phenyleneterepthalamide);
PPIA = poly(*p*-phenyleneisophthalamide);
PPTA = poly(*p*-phenyleneterephthalamide)

Liquid crystalline polymers are divided into three classes based on their chemical structures: backbone, side-chain, and mixed-configuration types. Predictions and explanations of the structural characteristics of low molecular mass compounds expressed as liquid crystallinity have been investigated in detail. These predictions are also applicable to liquid crystalline polymers. Important factors affecting liquid crystallinity are pressure, density, temperature, and chemical structure (degree of polymerization and properties of the repeating units, i.e., length, shape, intrachain rotational energy, dipole moment, site – site polarizability) [19]. Polymer concentration is an important factor in lyotropic liquid crystalline polymers.

Most meta-oriented fibers are heat-resistant; they are regarded as the first generation of high-performance fibers. Research and development on these fibers was spurred by the strong demand for heat-resistant and flame-retardant materials for space programs or industrial use after World War II. Many attempts were made to commercialize heat-resistant fibers, but only a few were successful at that time.

Para-oriented fibers are considered the second generation of high-performance fibers; they are composed mainly of para-substituted residues, instead of the meta-substituted residues of the first generation.

Table 2. Examples of high-performance fibers

Polymer	Trade name or developmental name	
	Meta-oriented fibers	Para-oriented fibers
Aramid	Nomex (HT-1; Du Pont)	Kevlar (Fiber-B, PRD-49, HT-4; Du Pont)
	Teijinconex (Teijin)	Technora (HM-50; Teijin)
	Fenilon (former Soviet Union)	Terlon (former Soviet Union)
		Twaron (Arenka; Akzo)
	Apyeil (Unitika)	Vniivlon (former Soviet Union)
	KM-21 (Kuraray – Mitsui Toatsu)	
Engineering polymers		
Poly(phenylene sulfide)	PPS (Phillips)	
Polyetherether ketone	PEEK (ICI)	
Polyether-imide	ULTEM (General Electric)	
	PI 2080/P8,4 (Dow – Lenzing)	
Novoloid (cross-linked phenolic resin)	Kynol (Gun-ei Chem. – Nippon and American Kynols)	
Polyamidehydrazide		X-500 (Monsanto)
		X-715 (Monsanto)
Polyarylate		Vectran (Kuraray – Celanese)
		Econol (Sumitomo Chemical – Unitika)
Polyazole	Celazole (Celanese)	PBT, PBO (Stanford Research Institute International – Dow)
Poly(amide – imide)	Kermel (Rhône – Poulenc)	
Polyimide	Arimide (former Soviet Union)	
Ladder polymer	BBB (J.E.Mark – Celanese)	
Chelate polymer	Enkatherm (Akzo)	

Compared to meta-oriented fibers, highly sophisticated polymerization and production techniques are needed for the para-oriented type to overcome difficulties caused by their rigid molecular structure. Du Pont initiated the second generation with Kevlar, a successor to the

first-generation Nomex. A tremendous amount of competitive research and development work has been undertaken in the industrialized countries. Despite these efforts, some fibers have had to be withdrawn at the developmental stage. Nevertheless, commercial exploitation has continued; HS and HM fibers have been introduced in conjunction with the development of composite materials (→ Composite Materials, Chap. 4.1.2.; → Reinforced Plastics).

Fibers from engineering polymers such as poly(phenylene sulfide), polyetherether ketone, and polyetherimide are attracting attention as a way to fill the gap between commodity fibers and first-generation heat-resistant fibers. The improved ratio of performance to cost is also attractive, as are the unique characteristics of this class of fibers; although they are melt-spinnable, they still have good thermal, mechanical, heat-adhesive, and chemical resistance properties.

Some typical high-performance fibers, including those that have not been commercialized, are listed in Table 2.

2. Heat-Resistant Fibers

2.1. Introduction

Polymers used for heat-resistant fibers are based on a comparatively simple concept of molecular design. The melting point (T_m) of polymers can be described by the formula

$$T_m = \Delta H / \Delta S$$

where ΔH and ΔS are the enthalpy and entropy of fusion, respectively.

The enthalpy of fusion can usually be increased by introducing symmetrical, rigid, or planar structures into the molecular backbone. The entropy of fusion can be decreased by introducing planar structures or polar linkages, such as amide bonds, into the molecular chain. For example, aramids have high melting points and high glass transition temperatures owing to strong intermolecular interactions between the aromatic residues and the amide linkages in their chain structures. In addition, the chemical structure of most wholly aromatic polymers makes them stable against moisture and oxidation. This conforms with the properties of cross-linked polymers (e.g., novoloid polymers) because the polymers are expected to have a rather small entropy of fusion in the softening stage even though they do not exhibit a well-defined melting point.

New technologies are required for the polymerization and spinning of heat-resistant fibers because the processing qualities of heat-resistant polymers are usually not as good as those of commodity fibers. Most of the problems are caused by a relatively high melting point and poor solubility. These problems can be overcome by using the solution polymerization–spinning method with polar solvents. Alternative approaches are cross-linking or additional solid-phase polymerization after melt spinning. For melt-spun fibers, sophisticated fiber production technologies have had to be developed, for example, increasing the degree of polymerization or improving the stabilizer, spinning equipment, and spinning conditions.

Solution spinning, melt spinning, and other aspects of fiber production discussed in this article are described in detail elsewhere (see → Fibers, 3. General Production Technology).

2.2. Solution-Spun Heat-Resistant Fibers

2.2.1. Aramid Fibers

Polymerization and Spinning. Combinations of aromatic diamines and aromatic dicarboxylic acids yield a variety of aramids, many of which are processed into fibers. Excellent review articles are available on the thermal and physical properties of these fibers [1], [20]. This section describes mainly meta-oriented aramid fibers of industrial importance.

Since Du Pont commercialized Nomex in 1967, various combinations of processes have been proposed for the production of aramid fibers based on poly(*m*-phenyleneisophthalamide) (PMIA) (Fig. 3). The polymer is prepared by low-temperature solution polymerization or interfacial polymerization according to the following reaction [21]:

Figure 3. Production processes for PMIA fibers

In both the solution and the interfacial methods, the following factors are important for the preparation of a high molecular mass polymer: use of high-purity monomers, stoichiometric balance of the two parent monomers, and minimization of the water content of the polymerization system. A small amount of a monofunctional compound such as aniline is generally used to control the degree of polymerization (Fig. 4) [22].

Polar amide solvents such as *N,N*-dimethylacetamide [*127-19-5*] are used in *low-temperature solution polymerization* [23]. These solvents are not only superior with regard to solubility but are also effective in activating electrophilic reagents. They act as acceptors of byproduct HCl, as well. Spin dope is obtained by neutralizing byproduct HCl with calcium hydroxide (Fig. 3, route A). This solution coagulates poorly in wet spinning because of the high content of calcium chloride and water. Accordingly, dry spinning is adopted in the Nomex process; residual calcium chloride and solvent are removed subsequently by water and heat treatment, respectively [24].

Interfacial polymerization is carried out at the interface between a cyclic ether solvent, such as tetrahydrofuran [*109-99-9*], and an aqueous alkaline carbonate solution as an acid acceptor (Fig. 3, route B) [25]. Polymers produced by the interfacial method contain a larger proportion of low molecular mass oligomers than those obtained by the solution method; this decreases the thermal stability of the fibers. In an improved interfacial method used by Teijin [26], preliminary oligomerization is carried out in tetrahydrofuran, and the resultant stoichiometric mixtures are subjected to interfacial polymerization (Fig. 3, route C) [27]. Subsequently, the powdery polymer is dissolved in *N*-methylpyrrolidone at a concentration of 20 – 23 wt % [28], and the resultant spin dope is wet-spun in aqueous calcium chloride solution [29]. The as-spun fiber is preoriented and subsequently hot-drawn at 200 – 350 °C.

Two modified processes have been proposed to overcome the poor coagulation of spin dope in the wet-spinning method. One utilizes a coagulant that gives void-free, as-spun fiber with high transparency [30]; The other involves reducing the calcium chloride content in the spin dope by removing hydrogen chloride in the form of ammonium chloride, a byproduct of the pre-

polymerization step (Fig. 3, route D) [23], [31], [32].

Figure 4. Control of the molecular mass of PMIA by addition of aniline [22]
Addition of aniline gives a wider molar ratio range for controlling η (i.e., molecular mass) within the limits 1.7 – 1.8 (compare $a_0 \rightarrow b_0$ and $a_1 \rightarrow a_1'$). P_0 and P_1 denote the maximum molecular mass with and without aniline, respectively.
∗ In aramid technology, molecular mass is usually expressed as a logarithmic viscosity number $\ln(\eta/\eta_0)/c$ (η = viscosity coefficient of solution, η_0 = viscosity coefficient of solvent, c = polymer concentration, dL/g).

Poly(*m*-phenyleneisophthalamide) is fusible in an inert atmosphere, although decomposition proceeds simultaneously in the molten state. Teijin has proposed a melt process for producing filaments by using a special spinneret, which has only its exit surface heated to avoid thermal decomposition [33].

The Mitsui Toatsu and Kuraray group has developed a new aramid fiber KM-21. Because the fiber is produced by polymerizing an aromatic isocyanate and aromatic carboxylic monomers, it differs from the foregoing PMIA fibers with respect to its chemical structure, production, and properties. However, its exact chemical structure and production method have not been made public [34].

$$\mathrm{OCN{-}Ar^1{-}NCO + HOOC{-}Ar^2{-}COOH} \longrightarrow \mathrm{\left[HN{-}Ar^1{-}NH{-}OC{-}Ar^2{-}CO\right]_n + CO_2}$$

where Ar = aryl

Fiber Properties. Important properties of meta-oriented aramid fibers are summarized in Table 3. The heat resistance and flame retardance of these fibers are better than those of commodity textile fibers. The physical properties of Teijinconex, a typical PMIA fiber, follow [35]:

Degree of crystallinity	35 – 39 %
Degree of orientation	90 – 93 %
Crystallite size	3.5 – 3.9 nm
Birefringence index	0.14 – 0.15
Density	1.37 – 1.38, g/cm^3

The moisture regain of this fiber is about 5 % under standard conditions (21 °C, 65 % R.H.) and 9 % at 95 % R.H., which is between equivalent values for cotton and nylon fibers.

Mechanical Properties. Most of the mechanical properties of PMIA fibers are about the same as those of commodity fibers (see Table 3). However, their wear resistance, both flexural and frictional, is lower than that of nylon or polyester fibers.

Weatherability and Dyeability. The weatherability of PMIA fibers is not inferior to that of nylon fiber, as far as strength retention is concerned (Fig. 5) [35]. However, the whiteness of PMIA deteriorates because the light-induced Fries rearrangement occurs readily.

Figure 5. Weatherability of PMIA fiber [35]
a) Nylon; b) Teijinconex (PMIA); c) Polyester

Fibers from wholly aromatic polymers are, in general, highly sensitive to light exposure and poorly dyeable. Intrinsic color is a defect of wholly aromatic polymers, particularly when they are used for textile materials. Only PMIA

∗ Composition unknown; made by polymerizing aromatic isocyanate and aromatic carboxylate monomers.

is colorless and can thus be employed in dyed textiles.

Methods proposed for dyeing PMIA fibers include the use of carriers, cationic dyes, or dope dyeing. Attempts to improve dyeability have involved modifying the fiber structure [40] and blending PMIA with other polymers [41]. Most fiber manufacturers have their own proprietary products featuring improved dyeability or lightfastness.

Figure 6. Strength retention in PMIA fiber exposed to dry heat [35]

The limiting oxygen index (LOI) is an important measure of flame retardance and represents the percent concentration of oxygen needed for self-supporting combustion. The LOI values of meta-oriented aramid fibers are given in Table 3.

Heat Resistance and Flame Retardance. Because PMIA exhibits high crystallinity and strong intermolecular cohesion due to hydrogen bonding, it has a high melting point and a high decomposition temperature. Accordingly, PMIA fibers have better thermal properties than commodity fibers. At elevated temperature, PMIA fibers offer better long-term retention of mechanical properties than commodity fibers; they also have good dimensional stability.

In the thermogravimetric analysis curve of a PMIA fiber, the decomposition temperature is 400 – 430 °C. Mechanical properties are almost unchanged down to −35 °C, and the fiber is still flexible with slight hardening.

Teijinconex (PMIA) staple fiber shrinks only 1 % at 250 °C (dry heat) and 5 – 6 % up to 300 °C. Long-term heat resistance of the fiber at various temperatures is shown in Figure 6.

Unmodified PMIA fibers shrink in a high-temperature flame. Improvement in dimensional stability and flame retardance has been achieved by treating PMIA fibers or fabrics with halogen, sulfur, and phosphorus compounds (e.g., Cl_2, Br_2, molten sulfur, $SOCl_2$, SO_2Cl, $POCl_3$, $POBr_3$, PCl_3, PCl_5) [42] and by blending with fibers that shrink less, such as Kevlar [43]; some products are available in flame-retardant grades. Thermal properties can be improved markedly by replacing one of the meta monomers by a para monomer as in PMTA (see Fig. 2). A self-

extinguishing PMTA fiber has even been developed [44]. The KM-21 fiber is also self-extinguishing and has a higher heat resistance than PMIA fibers (see Table 3).

Uses. Because of the excellent properties of PMIA fibers (e.g., high thermal and chemical resistance, as well as radiation resistance), their end uses are growing. Typical applications follow.

Clothing. Meta-oriented aramid fibers do not ignite, flare, or melt and stick to the skin. This makes them suitable for heat-resistant clothing material in the following areas:

1) heated furnaces: work uniforms, aluminized coats and pants, capes and sleeves, gloves and mitts, leggings, and spats;
2) emergency services: aluminized proximity suits, turnout coats and jumpsuits, station uniforms, rescue uniforms, fire-fighting and aviation garments, riot police uniforms, ranger uniforms, gloves, underwear, leggings, and spats;
3) fuel handling: work uniforms, rubber coats, gloves, socks, underwear, etc.

Interior Fittings. Materials from PMIA are used in aircraft interiors (for increased safety and enhanced flame retardance).

Industrial Materials. Uses here include filtration fabrics (especially filter bags for hot stack gases); high-temperature heat insulants (especially replacing asbestos); reinforcement in fire hoses, V-belts, and conveyor belts; threads for high-speed sewing; and cut-fiber reinforcement for rubber composites.

Electrical Insulation. High-temperature paper insulation for electric motors, dynamos, transformers, and cables; braided tubing for wire insulation; and dryer belts for papermaking are among the uses of PMIA fibers.

Miscellaneous Uses. Home ironing-board covers and kitchen gloves are also made from PMIA fibers.

2.2.2. Polyazole and Polyimide Fibers

Three types of wet-spun polyazole and polyimide fibers important for industrial and military uses are discussed:

1) polybenzimidazole fibers (e.g., Celazole),
2) poly(amide – imide) fibers (e.g., Kermel), and
3) polyimide fibers (e.g., Arimide).

Fiber Production. The polymer structure of the *polybenzimidazole (PBI) fiber* Celazole [*25734-65-0*] manufactured by Celanese is:

Production is described in detail in [45]. Polymerization is carried out in two steps. The first step involves conventional melt polymerization to yield a low molecular mass polymer with an intrinsic viscosity of 0.2 – 0.3 dL/g. The product is porous due to the formation of gaseous byproducts such as phenol and water. In the second step, this porous prepolymer is crushed to a fine powder and heated gradually to 380 °C to produce a fiber-grade polymer with an intrinsic viscosity $\geqq$0.75 dL/g. Both steps are carried out under a nitrogen atmosphere.

The polymer is powdered and dissolved in *N,N*-dimethylacetamide at a concentration of ca. 23 wt %. Lithium chloride in *N,N*-dimethylacetamide is reported to form a better solvent system for PBI than the acetamide alone.

A PBI fiber is obtained by dry spinning from a filtered dope, followed by drawing the as-spun fiber under a nitrogen atmosphere. The fiber obtained has excellent flame retardance, although heat shrinkage is appreciable. The sulfonation of imidazole residues in the PBI greatly improves its dimensional stability in flame-retardance tests.

Kermel (Rhône – Poulenc) is an example of a *poly(amide – imide) (PAI) fiber* [46].

Polymerization is carried out in a polar amide solvent to form the precursor polymers.

Kermel CAS registry numbers
X = O [*27084-44-2*], [*25038-81-7*]
X = CH_2 [*25821-35-6*]

A spin dope of PAI is obtained by in situ imidation of the precursor polymer [poly(amide – amic acid)] in solution by heating to ca. 100 – 120 °C; *N*-methylpyrrolidone is used as a solvent. The PAI fiber is spun from the dope and subjected to heat treatment.

In the case of *polyimide (PI) fiber* [47], spin dope containing poly(amic acid) is obtained. A precursor fiber is spun from the dope and then converted to PI fiber by heating, because PI is insoluble in amide solvents whereas its precursor polymer is readily soluble.

In Arimide fiber [*25036-53-7*] and [*25038-81-7*], X is oxygen.

Poly(bisbenzimidazobenzophenanthroline) [*39319-28-3*] (BBB) fiber attracted the attention of many polymer chemists and fiber scientists when it was reported by MARVEL et al. [48].

The fiber has excellent heat resistance, but no commercial product is known.

The BBB polymer is a double-stranded *ladder polymer* with a very high heat resistance. Ladder polymers have relatively high melting points and excellent weight retention as a function of temperature. However, ladder polymers are difficult to spin into fibers because of their low tractability.

Properties and Uses [49], [50]. Properties of typical PBI, PAI, and PI fibers are listed in Table 4. Polybenzimidazole fiber was developed in response to the needs of the U.S. Air Force to satisfy special requirements for the NASA space program. Its moisture regain is similar to that of wool, and its modulus is lower. Of fibers known at present, PBI has the highest LOI value; it tends to compete against PMIA fibers in its applications but is more expensive. Applications should exploit its resistance to chemicals and high temperature; they include

1) thermal-protection clothing: garments for fire fighters, industrial work uniforms, space and military flight suits, underwear and escape suits, and other aerospace materials;
2) high-temperature filtration: high-temperature filters (e.g., flue-gas filters); and
3) asbestos substitute: protective gloves for high-temperature uses.

The uses of meta-oriented PAI and PI fibers are similar to those of the meta-oriented aramid fibers. Kermel (PAI fiber) is used in underwear for pilots or operators of armed tanks because the resulting fabric is more supple than aramid fabrics.

Table 4. Properties of heat-resistant polybenzimidazole (PBI), poly(amide – imide) (PAI), and polyimide (PI), staple fibers

Property	PBI fiber (Celazole, Celanese) [49]	PAI fiber (Kermel, Rhône – Poulenc) [50]		PI fiber (Arimide, former Soviet Union) [47]

2.3. Melt-Spun Heat-Resistant Fibers

2.3.1. Novoloid Fibers (→ Phenolic Resins)

Fiber Production. The melt-spinning method has the advantage of eliminating the need for solvent recovery; however, melt-spun fibers are less heat-resistant than solution-spun fibers. Kynol [*9003-55-8*], a commercial novoloid fiber, exhibits exceptionally high heat resistance because cross-linking occurs after melt spinning. Kynol is produced from a novolac polymer by melt spinning [52] and subsequent cross-linking with formaldehyde [53]. The as-spun novolak reacts with formaldehyde in the presence of an acid catalyst to form cross-linked networks of methylene and dimethylene ether bonds.

Kynol [*9003-55-8*]

Novoloid fiber was first developed by Carborundum as a carbon-fiber precursor and commercialized in the 1970s as a heat-resistant fiber [51]. It is produced by Gun-ei Chemicals and distributed by Nippon Kynol and American Kynol [54], [55].

Properties. One of the most remarkable features of novoloid fiber is its flame retardance. It generates virtually no smoke or gas. It has high LOI values and can be converted to carbon fibers without melting or shrinkage by heating in an inert atmosphere.

Kynol shows good thermal stability at 150 °C in air and 200 – 250 °C in the absence of air. Its chemical stability is also excellent. Kynol has excellent heat-insulation and acoustic properties. Its density is relatively low compared to other heat-resistant fibers.

The weatherability and light stability of Kynol are moderate. Dyeability is limited because of its intrinsic golden-brown color. Textile properties of Kynol fibers follow [56], [57]:

Diameter	14 – 33 µm
Density	1.27, g/cm^3
Tensile strength	0.15 – 0.20 GPa
Elongation at break	30 – 60 %
Tensile modulus	3.3 – 4.4 GPa
Loop strength	0.2 – 0.35 GPa
Knot strength	0.12 – 0.17 GPa
Elastic recovery (3 % elongation)	92 – 96 %
Moisture regain (20 °C, 65 % R.H.)	6 %
LOI	30 – 34

Uses. Novoloid fiber is used as reinforcement in resins and rubber to improve properties such as heat resistance, electrical insulation, and dimensional stability. Further applications are in cable material, brake material, various industrial sheets (e.g., welders' protective sheet, workplace shielding sheet), and safety products for accident prevention.

2.3.2. Fibers from Engineering Plastics

Fiber Production. Progress in both polymerization and fiber production technologies in the field of engineering plastics has stimu-

lated melt spinning of fibers from such plastics as poly(phenylene sulfide) [*9016-75-5*] (PPS) [57], polyetherether ketone [*31694-16-3*] (PEEK) [58], and polyetherimide (PEI) [58]; P84 [*65328-60-1*] fibers have also been reported [59]. Polymers for fiber production must have higher molecular masses than those used for plastics. They are spun into fibers in processes similar to conventional melt spinning (→ Fibers, 3. General Production Technology, Chap. 3.1.2.).

Some important technical problems are as follows:

1) The spinning apparatus must be improved to prevent gel formation at the surface of the spin die.
2) Spinning should be performed with a relatively viscous polymer melt.
3) The moisture content of the polymer chips should be reduced.

Properties and Uses. Properties of heat-resistant PEEK, PEI, and PPS fibers are listed in Table 5. The fibers normally have a better heat resistance than commodity fibers. They also offer an attractive performance – cost ratio.

Thermoplastic engineering polymers that can be utilized in fibers are also useful for composite materials. For example, PEEK fiber can be hybridized with carbon fibers for aircraft materials (usually called FF or fiber – fiber composite) [60]. Fiber – fiber composite has several advantages over conventional composites because its production does not involve prepregnation. Rationalization of the process and the better shapability of the matrix components (e.g., PEEK fiber) are definite advantages of FF composite technology.

Fiber making from high-performance thermoplastics is still in the developmental stage. Nevertheless, prospects for the further development and early commercialization of PEEK, PPS, and PEI fibers are promising.

Several reports on PPS fibers have cited their good dimensional stability, heat resistance, nonflammability, chemical resistance, and electrical properties [61]. Filtration fabric for baghouses of coal boilers is one promising application of PPS. Because of its high nonflammability, it could also be used for interiors and other parts of aircraft.

3. High-Strength and High-Modulus (HS – HM) Fibers

3.1. Introduction

Du Pont was successful in developing Nomex as a heat-resistant fiber in 1967, and Kevlar as a high-strength and high-modulus (HS – HM), poly(*p*-phenyleneterephthalamide) (PPTA) fiber in 1973. As a new member of the PPTA class, Twaron (Akzo) became available in 1986. Terlon [*63428-84-2*] (former Soviet Union) is also considered a member of the PPTA family, as is Technora (Teijin) which was commercialized in 1987.

The PMIA fiber-making technologies are based mainly on those of conventional solution-spun fibers such as rayon and polyacrylonitrile. The outstanding mechanical properties of Kevlar are achieved by using liquid crystalline (i.e., anisotropic) dope for fiber spinning. Spinning of anisotropic dope opened up a new era for HS – HM fibers. This concept has also been applied to making fibers from other liquid crystalline polymers, both lyotropic and thermotropic. Polyamidehydrazides [62] and polyazoles [63] belong to the lyotropic class, whereas polyarylates [64], polyazomethines [65], poly(amide – ethers), and poly(amide – esters) [66] are thermotropic polymers (Fig. 7).

As Flory et al. predicted [67] in 1956, a polymer with an essentially linear structure gives a nematic liquid crystalline solution in concentrated sulfuric acid when the polymer concentration exceeds a certain critical value. As shown in Figure 8, the viscosity of the solution increases with concentration in the optically isotropic region and reaches a maximum. At concentrations above this maximum, the solution starts to become optically anisotropic (liquid crystalline) and its viscosity passes through a minimum before finally increasing again [68].

The use of liquid crystalline dopes in the spinning process results in several advantages. A highly oriented fiber is obtained without the need for hot drawing. Anisotropic spinning can be carried out with a more highly concentrated dope than isotropic spinning. Panar et al. have reviewed solution spinning with regard to the

structure and properties of anisotropic aramid solutions [69].

Research and development work on HS – HM fibers has continued. In particular, an extraordinarily HM fiber is obtained by spinning rod-shaped polymers, such as para-oriented polyazole [70], [71].

Figure 8. Viscosity as a function of polymer concentration and temperature [68]

Figure 9 shows the specific tensile strengths and moduli of organic and inorganic HS – HM fibers [72].

3.2. Solution-Spun HS – HM Fibers

Solution-spun HS–HM fibers that are already available or being developed are listed in Table 6 together with their chemical structures.

3.2.1. Para-Oriented Aramid Fibers

3.2.1.1. Production

Poly(*p*-phenyleneterephthalamide) [*24938-64-5*] (PPTA), a typical para-oriented aramid, is formed by the reaction

Hexamethylphosphoric triamide [*680-31-9*] was formerly used as a solvent in PPTA production. Since the toxicity of the amide was announced by Du Pont [73], several alternative solvent systems have been developed; these include polar amide solvents, which are particularly effective at higher concentrations of metal chlorides such as calcium chloride [74–76]. International legal conflict occurred between Du Pont and Akzo because Du Pont owned several patents relating to dope formation and the spinning of PPTA fibers, whereas Akzo owned the patents regarding polymerization. However, in 1988, both firms agreed to cross-license each other's patents [77].

The polymerization feed is an isotropic monomer solution; the mixture goes through an anisotropic state, and solidification occurs toward the end of the polymerization. Continuous stirring – shearing is important in order to obtain high molecular mass polymers, because the reaction mixture behaves like a Bingham fluid and exhibits plastic flow with a yield value [77]. During chain growth, mechanical shear stress applied to the polymerization mixture produces short, pulplike fibers without the need for a spinning step [78–80].

The production of PPTA fibers is summarized in Figure 10A. At a concentration of about

20 wt %, PPTA gives an anisotropic spin dope suitable for dry-jet wet spinning at about 80 – 90 °C (Kevlar 29 fibers). In conventional wet spinning, the spin die (or cap) is located in the coagulation bath. However, in dry-jet wet spinning an air gap is provided between the cap surface and coagulation bath. The dry-jet wet spinning method offers the following advantages over conventional wet spinning:

1) At equivalent polymer concentrations a lower solution viscosity can be used because the dope temperature can be higher than that of the coagulation bath.

Figure 10. Production of HS – HM aramid fibers [82], [83], [88]
A) Kevlar and Twaron PPTA fibers; B) Technora fibers produced from a copolymer of PPTA
Polymer structures of the fibers are given in Table 6.

Figure 11. Structural models for PPTA fibers
A) "Skin – core" model [93], B) "Pleated sheet" model [95]

2) At equivalent solution viscosities a higher polymer concentration can be used, which improves the coagulation properties of the spun fiber.
3) The method favorably affects the coagulation properties of the spun fiber because the fiber surface releases a small amount of solvent as it passes through the air gap, and its temperature decreases.

The spin dope solidifies at room temperature and shows a sharp melting point at 79 – 80 °C. On the basis of X-ray diffraction data [81], the solidified dope is regarded as a crystal solvate or crystalline polymer complex. A crystal solvate is also observed in meta-oriented PMIA as a reflection of its polar structure [82].

"Anisotropic" spinning produces HS – HM fibers that have adequate mechanical properties even in the as-spun state [83]. The modulus can be improved by heat treatment of the as-spun fiber (Kevlar or Kevlar 29 fibers) [84].

Theoretical fiber moduli have been estimated for a variety of polymers [85], [86]. The tensile fiber modulus of Kevlar 149, announced by Du Pont [87], agreed with the value predicted for PPTA.

However, HS – HM fibers from semirigid aramid copolymers (e.g., Technora fibers from a copolymer of terephthalic acid and a diamine mixture consisting of 3,4′-diaminodiphenyl ether and *p*-phenylenediamine) can be produced by using the isotropic dope adopted in the meta-oriented aramid. The reaction mixture obtained by solution polymerization is then neutralized to give a spin dope, which is subjected directly to dry-jet wet spinning. The as-spun fiber is superdrawn (i.e., a very high draw ratio) at high temperature after the residual solvent is driven off [88]. Because only a single solvent is used throughout and the polymer does not have to be isolated, fiber production becomes very simple (Fig. 10B).

The most characteristic feature of the fiber is its exceptionally high drawability, which is significantly higher than that of nylon and polyester [89]. This property may be due partly to flow orientation from the thermotropic liquid crystal, but this has not been verified because the polymer starts to decompose before forming a clear melt.

3.2.1.2. Properties

Para-oriented aramid fibers all have high tenacity, high tensile modulus, and high heat resistance, which reflect their highly oriented rigid molecular structure. The properties vary slightly, however, with the chemical structure of the polymer and the microfine structure of the fiber. Several structural models have been proposed for PPTA fibers; Figure 11 shows the *skin – core* [69], [90–93] and *pleated sheet* models [94], [95].

Properties of Kevlar [87], [96]. The regular products are Kevlar, Kevlar 29, and Kevlar 49.

Mechanical Properties. Kevlar 149 has a higher modulus, and Kevlar HT [97] a higher tenacity, than the early Kevlar fibers (see Table 7). New brands of Kevlar such as Kevlar 68 and colored Kevlar have been announced in 1988 [96].

Kevlar 149 exhibits the highest tensile modulus of all commercial organic fibers, nearly twice that of E-glass but lower than that of carbon fiber from polyacrylonitrile. In contrast, its compressive properties are inferior to those of glass and carbon fibers. Kevlar displays structural defects ("kink bands") and buckling under compressive stress (see Fig. 12). This phenomenon is reported to correspond to the transition of carbon – nitrogen bonds in the amide group from the usual trans to the cis conformation [99]. The fiber will have further applications if its compressive strength is improved. This may be realized by reinforcement design improvements (→ Composite Materials).

Figure 12. "Kink bands" in compressed PPTA fiber (×4500)

Thermal Properties. Kevlar shows no heat shrinkage up to 160 °C and remains stable below 180 °C for long periods. Although some scientists classify PPTA as a nonmelting polymer (i.e., the melting point exceeds the decomposition point), it is reported to have a melting point measured by differential thermal analysis [100]. The polymer carbonizes at approximately 430 °C. It is self-extinguishing and has an LOI value of 29.

Chemical Resistance. Kevlar has comparatively high chemical resistance to organic solvents (e.g., acetone, methyl ethyl ketone), sodium chloride solution, and hot water. However, its resistance to strong acid and strong alkali is inadequate (cf. Fig. 13).

Weatherability. Because the weatherability of Kevlar is not as good as that of other synthetic organic fibers, a protective coating is needed when the fiber is exposed to ultraviolet light.

Fatigue Properties. Kevlar has a tensile fatigue resistance almost comparable to that of nylon and polyester [101], but its flexural fatigue resistance is poorer [102]. Wear fatigue resistance is also poor because of the tendency toward fibril formation [103].

Figure 13. Resistance of para-oriented HM – HS aramid fibers (Technora and PPTA) to sodium hydroxide and sulfuric acid [88]
a) Tenacity;b) Intrinsic viscosity

Properties of Twaron Fiber. Being similar in chemical structure, Twaron is almost identical to Kevlar in many of its properties; see Table 7 [104].

Properties of Technora Fiber. Technora fiber (a PPTA copolymer) has excellent *mechanical and thermal properties* (Table 7) [105]. Its tensile strength is higher than that of PPTA fibers, whereas its tensile modulus is lower than that of high-modulus PPTA fibers.

Technora is an excellent heat-resistant organic fiber, although its thermal decomposition temperature is somewhat lower than that of PPTA fibers. Strength retention in dry heat is excellent. The LOI value of 25 is somewhat lower than that of PPTA fibers.

Chemical Resistance. Technora is highly resistant to hypochlorous acid and most organic chemicals. One characteristic feature is its extremely high chemical resistance to strong acid and alkali, which exceeds that of PPTA fibers [88]. The fiber deteriorates and its strength declines because its inherent viscosity decreases (Fig. 13).

The excellent chemical resistance of Technora presumably stems from its molecular structure of ether linkages, its microfine structure that prevents fibril formation, and its fine surface structure.

Fatigue Properties. Technora's comparatively high fatigue resistance may derive from the flexibility of its copolymer chain and the rather loose crystal structure, which minimizes fibril formation [102].

Para-oriented aramid fibers have a variety of outstanding properties, but some effort is still needed to improve their poor dyeability and poor adhesion to fiber-reinforced plastic matrices.

3.2.1.3. Uses

Because of their excellent mechanical and thermal properties, para-oriented aramid fibers are used widely as industrial materials (rope, cable, lightweight tension members); asbestos substitutes; antiballistic materials; and reinforcement

fibers in rubber (tires, belts, hoses, etc.), fiber-reinforced plastics including thermoplastics, fiber-reinforced metals, and fiber-reinforced cement or concrete. Typical applications are listed below.

Antiballistic Materials. Para-oriented aramid fibers are used in bulletproof jackets and boards, as well as in military helmets.

Tire Cord. Para-oriented aramid fibers can replace steel in tire cord. Consumption is low, however, primarily because of their high cost (a definite drawback of para-oriented aramid fibers), but also because of their inadequate adhesion to rubber and poor compressive fatigue properties. To increase their use, the price must be lowered and the properties improved.

Belts. Para-oriented aramid fibers are being considered for use as core cord for rubber belts; applications in synchronous power transmission belts and variable-speed belts in automobiles are especially promising. The fibers are also used as core cord for belts in continuously variable transmissions [106]. In 1986, Bridgestone Cycle began selling "Bellrex" bicycles, in which a belt reinforced with para-oriented aramid fiber replaces the metal chain [107]. Use of these fibers in conveyor belts has also been studied.

Hoses. Para-oriented aramid fibers are promising as reinforcement material for high-pressure hoses, heat-resistant hoses, and the heat-resistant radiator hoses of snowmobiles.

Composites. Composite materials are regarded as a use of aramid fibers (→ Composite Materials, → Reinforced Plastics).

Rope. Ropes utilizing the high specific strength of para-oriented aramid fibers are promising in the field of undersea development (e.g., ropes for offshore drilling rigs). Because of their light weight and high corrosion resistance, they are expected to replace metal chains and wire ropes. However, para-oriented aramid fibers are inadequate with regard to weatherability and wear resistance, and require a suitable coating (e.g., polyethylene).

Cable. The fibers are promising for the tension members of optical-fiber cables and are already being used as such.

Fiber-Reinforced Cement and Concrete. Asbestos and steel have conventionally been used to overcome the brittleness of cement and concrete, but health and corrosion problems create a need for new substitutes. Reinforcing concrete with chopped HS – HM fibers prevents cracking, and enhances both flexural and tensile strength [108], [109]. Fiber-reinforced concrete and cement are thus expected to be useful construction materials, for example, in curtain walls, floors, and ceilings.

Plastic rod with continuous-filament reinforcement is being developed. Its primary intended use is to replace steel in prestressed concrete, thereby eliminating corrosion problems [110].

Protective Clothing. The excellent cutting and piercing resistance of para-oriented aramid fibers is being exploited in protective materials used, for example, in safety gloves and work clothes for chain-saw operators.

Protective Materials. Para-oriented aramid fibers have excellent antiballistic properties, presumably due to their high tensile strength, high modulus, heat resistance, and easy fibril formation [111]. The typical use is in bulletproof vests and jackets.

3.2.2. HS – HM Fibers from Some Aramid-Related Polymers

A series of HS – HM fibers from aramid related polymers have followed the same pattern of development of para-oriented aramid fibers. The fibers (polyamidehydrazide, polyhydrazide, polyoxadiazole, polyamidehydrazide – oxadiazole) have analogous chemical structures and similar thermal and mechanical properties to PPTA fibers.

Monsanto has announced the development of X-715 (polyazolehydrazide) [112] and X-500 (polyamidehydrazide) fibers [113]; for structures, see Table 6. No commercial use of the fibers has been reported.

3.2.3. Polyazole and Polyimide Fibers

Fiber scientists in pursuit of an ultrahigh-modulus fiber have been concerned with perfectly linear polymers of rodlike molecular geometry. Although such fibers are expected to offer an extremely high modulus, the preparation of such high molecular mass polymers and the design of appropriate fabrication systems involve many difficulties.

3.2.3.1. Polyazole Fibers

Polyazoles used for fiber production are shown below:

Poly(*p*-phenylenebenzobisthiazole)
[*69794-31-6*], [*75855-83-3*] (PBT)

Poly(*p*-phenylenebenzobisoxazole)
[*60871-72-9*] (PBO)

Production. Rodlike polyazoles such as poly(*p*-phenylenebenzobisthiazole) (PBT) and poly(*p*-phenylenebenzobisoxazole) (PBO) can be made into ultrahigh-modulus fibers [71]. Iwakura et al. first proposed synthesizing polyazoles by using polyphosphoric acid as solvent [114]:

Wolfe et al. developed a sophisticated method for obtaining polymers with an intrinsic viscosity of 20 – 42 dL/g [63], [71]. Figure 14 shows the relationship between the intrinsic viscosity η and the molecular mass of the polymer [115], [116].

The liquid crystalline reaction mixture is used as the spin dope. Ultrahigh-modulus fibers are made by dry-jet wet spinning followed by heat treatment, in a process similar to that used for PPTA fibers (see Section 3.2.1.1).

As an extension of the rodlike polymers, fibers made of a molecular composite system have been proposed by Takayanagi et al. [117]. In this system, rodlike polymers are used as reinforcement and flexible polymers as the matrix component. An optically isotropic spin dope is used to make molecular composite fibers of polyazole [105], [118], or polyimide [119]. The reinforcing component in the molecular composite fiber system is reportedly well-dispersed in the matrix [120]. Such systems are attracting attention as new materials with excellent characteristics. Prospects for future development are promising because these fibers may exhibit unique characteristics not displayed by any known fiber. Production of a novel composite with a stress – strain curve totally different from those of its parent materials is conceivable.

Figure 14. Relationship between molecular mass and intrinsic viscosity of poly(*p*-phenylenebenzobisthiazole) [115], [116]
∗ AFWAL = Air Force Wright Aeronautical Laboratories (United States).

Properties and Possible Uses. The fiber structure of PBT is similar to that of PPTA; it is composed of well-grown fibrils. The fibers readily form kink bands under applied forces; the polymer crystals probably glide along the crystalline plane of the aromatic rings [121]. The approximate tensile strength of PBT is 3.1 GPa; its tensile modulus is 340 GPa [71]. The approximate tensile strength of PBO is 3.4 GPa; its tensile modulus, 410 GPa [71]. Although paraoriented polyazole PBT and PBO fibers have the best thermal and mechanical properties of all known organic fibers, no practical uses have been developed because of their high production cost.

3.2.3.2. Polyimide Fibers

Production. Fibers from rigid polyimides are expected to form HS – HM fibers with a reasonable performance – cost ratio, because highly linear molecular structures can be synthesized from less expensive monomers than in the case of para-oriented polyazoles. However, studies on rigid polyimide fibers have not advanced far because the polymers are infusible and mostly insoluble. Copolymerization makes the polymers tractable.

With regard to para-oriented polyimides, several research groups have obtained high-modulus polyimide fibers by incorporating a third component to make the polymer tractable. Kotton et al. have made a significant contribution to the area of high-modulus PI fibers [122].

Ube Industries has announced HS – HM fibers (Upilex) obtained from a spin dope that contains polyimides based on biphenyltetracarboxylic dianhydride in 4-chlorophenol [123]. The chemical structure of Upilex is given in Table 6.

Because poly(*p*-phenylenepyromellitimide) (PPPI) and poly(*p*-phenylene) (PPP) are neither fusible nor soluble, fibers cannot be produced directly from these polymers [124], [125]. If tractable precursor polymers can be found, they can be converted to PPPI or PPP fibers by thermal or chemical treatment. As of now, only brittle PPPI and PPP fibers can be produced.

Poly(*p*-phenylenepyromellitimide) [*26099-65-0*] (PPPI)

Poly(*p*-phenylene) [*25190-62-9*] (PPP)

Jinda et al. reported polyimide fibers from copolyimides based on pyromellitic dianhydride and substituted amines. They prepared the fibers by wet spinning the precursor poly(amic acid) solution and then imidating by thermal or chemical means [126]. Research on HS – HM polyimide fibers continues [127].

Properties and Possible Uses. Wholly aromatic polyimides rank among the most heat-resistant organic polymers. Despite a number of patents and research papers, PI fibers are not yet used commercially.

Some PI fibers have mechanical properties almost equivalent to those of para-oriented aramid fibers. Upilex fibers have a tensile strength of 2.9 GPa and a tensile modulus of 197 GPa [123]. The following polymer has a tensile strength of 2.6 GPa and a modulus of 151 GPa [126] (see top of this page).

The thermal properties of para-oriented PI fibers are better than those of PPTA fibers [123]. Their strength retention is better than that of PPTA fibers in a humid, saturated atmosphere at 200 °C. Weatherability is also better. Polyimide films are stable against radiation; this characteristic is also expected in PI fibers.

Para-oriented PI fibers, when available commercially, may be used in applications such as heat-resistant insulating materials, flameproof clothing, filter cloth, and atomic reactor materials.

3.3. Melt-Spun HS – HM Fibers

The success of Kevlar, based on the spinning of liquid crystalline polymers, triggered investigations of thermotropic para-oriented polyarylates [64]. Initially, use of these polymers was limited to engineering plastics, but it has been extended to fibers. Later, polyazomethine was found to form HS – HM fibers in the thermotropic state. Highly symmetrical polymers are infusible and, of course, insoluble because of their low affinity for polar solvents. Copolymerization or substitution of aromatic residues makes the polymers tractable. Typical fibers from thermotropic liquid crystalline polymers are shown below [128–130]:

Econol [*59763-21-2*] (Sumitomo chemical)

Vectran [*81843-52-9*] (Kuraray)

Polyazomethine [*61674-11-1*], [*61594-45-4*] (Du Pont)

Production. The rigid polyarylates are synthesized from derivatives of diphenols, dicarboxylic acids, and hydroxycarboxylic acids.

$$CH_3COO-Ar^1-OCOCH_3 + HOOC-Ar^2-COOH$$
$$+ CH_3COO-Ar^3-COOH \longrightarrow$$
$$\left[O-Ar^1-O-OC-Ar^2-CO\right]_n\left[O-Ar^3-CO\right]_m$$
$$+ CH_3COOH$$

where Ar = aryl

Melt polymerization is employed in most cases. The process is stopped when the melt reaches a viscosity suitable for spinning. The as-spun fibers are usually brittle. Subsequent heat treatment improves both the strength and the elongation because polymerization then continues in the solid phase, resulting in a further increase in molecular mass. This solid-phase polymerization takes rather long, and shortening the time is a pressing technical problem. Polyazomethine is produced by the following reaction:

It must be spun in the form of liquid crystalline oligomers [130] because (1) the melt viscosity is suitable for spinning and (2) the liquid crystalline form of the oligomers means that the fiber can be highly oriented.

JACKSON et al. have proposed the term "self-reinforced polymers" for injection-moldable arylate block copolymers that consist of a liquid crystalline polyarylate reinforcing component and a flexible polyester matrix component [131]. Melt-spun fibers from self-reinforced polyarylates are analagous to solution-spun fibers from molecular composites. Other fiber types based on self-reinforced polymers are known [132].

Properties. Econol [128] and Vectran [129] are being developed. Table 8 lists some of their physical properties.

Econol fiber, announced in 1985 by Sumitomo Chemical, is a three-component copolymer. Its strength and modulus are higher and its elongation at break lower than those of Vectran (Table 8). The fiber seems promising for use in lightweight materials. It has extremely low moisture regain.

Vectran, announced by the Kuraray–Celanese group, is a two-component copolymer. The molar ratio of the components has not been disclosed. Its chemical resistance is excellent; its tensile strength and modulus are somewhat inferior to those of Econol but better than those of PPTA fibers.

Polyazomethine fiber properties have been reported [130]. As-spun fibers have a tensile strength of 0.97 GPa and a modulus of 121 GPa, whereas the values after heat treatment are 5.83 GPa and 148 GPa, respectively. The fibers are in the research stage. They resemble polyarylate fibers because they are spun from a relatively low molecular mass polymer melt. The as-spun fibers are usually brittle, and subsequent heat treatment improves strength and elongation due to solid-phase polymerization in the fiber shape.

Possible Uses. Econol and Vectran have several desirable properties. At present, both fibers are still at the market-development stage. A variety of test specimens (e.g., multifilament, chopped fiber, yarn, monofilament) are available for research applications. Tire cords, rubber reinforcement in belts and hoses, ropes, cables, tension members for optical-fiber cables, friction materials, and reinforcement fibers for various composites are examples of applications.

Vectran may also be produced as a pulp that can replace asbestos.

Table 8. Physical properties of polyarylate and polyazomethine fibers

Property	Econol (Sumitomo Chemical) [128]	Vectran (Kuraray –Celanese) [129]	Polyazomethine (Du Pont) [130]
Density, g/cm^3	1.40	1.40	1.50
Tensile strength, GPa	3.4 – 4.1	2.9	5.83
Tensile modulus, GPa	129 – 139	64.4	148.1
Elongation at break, %	2.4 – 3.1	3.7	
Moisture regain, %	0.01	0	
LOI		37	

The physical properties of both Vectran and Econol are similar to those of para-oriented aramid fibers (see Section 3.2.1.2), and competition between these two classes and high-performance polyethylene fibers appears unavoidable. Therefore, suitable applications must be found in which the low moisture regain of the fiber is exploited. This approach offers a way of overcoming the high cost of this type of fiber.

Problems still to be solved for these fibers include poor adhesion to rubber and poor chemical stability. The fibers are attacked by components present in rubber (i.e., amines, decomposition products of vulcanization accelerators, and antioxidants) and moisture.

1. Introduction

Definitions. High-temperature materials are those materials that are used specifically for their heat-resisting capabilities for which the temperature criterion (*capability*) is expressed as the ratio of the maximum use temperature to the melting temperature (T_m) rather than simply as the maximum use temperature. Various material systems are compared on this basis in Table 1.

Mechanical properties and environmental resistance are major factors in the selection of such materials, but physical properties can also have a significant influence. Density is particularly important in rotating machinery. Thermal expansion coefficients are important in designs involving different materials in close contact, and thermal stress is controlled by the thermal expansion coefficient, thermal conductivity, and Young's modulus.

In economic terms, the most cost-effective material in any application is the material that satisfies the total operational requirement at minimum cost. The cost element must include consistency of component manufacture in relation to its specification.

Applications Requiring High-Temperature Materials. Thermal energy is used in three ways: (1) for conversion to mechanical or electrical power, (2) in processing materials and controlling the environment, and (3) as a sink for dissipating other energy forms by design or because of the inefficiency associated with another process. High-temperature technology is thus of major importance in many industries including primary metal and nonmetal production, material processing, chemical engineering, transportation, power generation, and domestic appliances. For many of these industries, the price of fuel is a major component of overall operating cost. Materials that allow operation at high temperature are essential for industrial competitiveness because the efficiency of fuel conversion and use is related to operating temperature. Current operating temperatures in various industries are shown in Figure 1 together with the melting temperatures of selected materials. Up to ca. 4000 °C more than one material option may exist, depending on operational requirements. However, no material is capable of operating above 4000 °C; here, thermal ablation must be used.

Many industries could benefit from higher operating temperatures than those currently in use. The temperature of superheater tubes for steam-raising boilers in power plants is currently 560 °C; if this could be increased to 650 °C, efficiency would increase from 35 to 36.5 %. Although the higher temperature produces a more aggressive environment and requires new materials, it would also result in saving ca. 3.5×10^6 t of coal per year, i.e., 4 % of the total coal used in the United Kingdom for power generation [8]. The use of ceramics in the development of diesel engines in the United States has allowed higher operating temperatures, thus improving efficiency (an increase from 38 to 65 % appears possible) and reducing exhaust pollution [9]. For a given thrust, the thermal efficiency and reduction in size of a jet engine can be improved by simultaneously increasing turbine entry temperature and avoiding the need to air-cool the turbine blades internally (Fig. 2) [10].

Table 1. Temperature capability of high-temperature material systems

Material	Approximate maximum use temperature, °C	Ratio of maximum use temperature (°C) to melting temperature (°C)	Application
Aluminum (RR 350)	300	0.45	stressed
Titanium (IMI 685)	550	0.33	stressed
Low-alloy steel	580	0.37	stressed
Austentitic steel (A 286)	600	0.4	stressed
Nickel superalloy (MarM 002)	1000	0.77	stressed
Corrosion-resistant austenitic steel	1150	0.75	unstressed
Nickel (Brightray H)	1250	0.9	unstressed
Ferritic corrosion-resistant steel (FeCrAl)	1350	0.9	unstressed
Alumina	1850	0.9	unstressed
Tungsten	2500	0.74	unstressed

Figure 1. Typical operating temperatures in high-temperature environments

Figure 2. Effect of turbine entry temperature and component cooling on thermal efficiency of a gas turbine
Temperatures are the takeoff turbine entry temperatures.

High-temperature materials also conserve energy by minimizing heat loss. Compared with conventional insulating firebrick furnace linings, for example, lightweight fibrous insulating materials provide more effective insulation, and their low thermal mass allows shorter cycle times and improved productivity. Such materials are widely used in heat treatment furnaces and ceramic firing kilns. Compared with earlier linings, they provide fuel savings of 25 – 50 % and halve process cycle times. A similar type of material, combined with an external radiating coating, is used to resist the high temperature developed by the space shuttle orbiter vehicle on reentry.

Operating Environment. High-temperature materials operate in environments with a wide spectrum of mechanical and chemical conditions. The temperature may be relatively constant (e.g., in insulating a continuously operated heat treatment furnace) or subject to severe cycling (e.g., in jet engines where the thin edges of turbine blades can experience temperature changes $> 1000\,°C$ in seconds). The operating stress can vary from high combined centrifugal and thermal stress in a gas turbine disk to very low stress levels in furnace heating elements. Erosion is another important mechanical environmental factor (e.g., in fluidized-bed coal combustion systems).

The fundamental chemical reaction occurring at high temperature is *oxidation.* Thus, some measure of inherent oxidation resistance is an essential characteristic of high-temperature materials; however, many applications involve significantly more complex corrosive environments than simple oxidation. In certain types of coal gasification, the atmosphere may be reducing to some extent: thus, alloys that rely on chromium oxide scales for protection do not perform as well as aluminum oxide-forming alloys, which remain stable even in severely reducing environments. Oxidation is further modified by atmospheric and fuel contaminants. An atmosphere with low oxygen activity that contains significant amounts of carbon-containing gases can cause carbon absorption, with consequent reduction in corrosion resistance of materials that depend on chromium oxide scales for protection. Atmospheric contamination with sulfates and chlorides (such as which may be experienced by gas turbine engines operating in coastal areas) can result in an accelerated form of corrosion known as *hot corrosion*. Another problem arises from the desire to use lower grade fuel (such as residual fuel oil) instead of higher fractions (such as kerosene) in industrial turbines and boilers. The lower grade fuels contain larger amounts of impurities such as vanadium, sulfur, and sodium, which accelerate corrosion.

The other major operating requirement, material lifetime, depends on the type of machinery, component, application, and environment. It can range from minutes for a rocket motor, through 50 000 – 100 000 h for industrial steam and gas turbines, to more than 20 years for large steam turbine installations (100 – 1000 MW). For many component applications, no single material system is able to meet all operational requirements; coatings are then required to provide corrosion resistance, insulation, and wear resistance.

Effect of Stress. Operational stress has a major influence on temperature capability, with the limit being $0.7 - 0.9\,T_m$ in unstressed applications and $0.3 - 0.7\,T_m$ in stressed applications (Table 1). Nickel superalloys are particularly useful with a stressed capability in excess of $0.7\,T_m$. The broad stress – temperature operational regimes of various materials in stressed applications are illustrated in Figure 3. The strength is based on the 0.2 % proof stress (PS) for metals and an appropriate proportion of the flexure strength for ceramics and composites. The position of carbon – carbon composite material depends on the volume fraction and number of directions of reinforcement. Specific strength (strength divided by density) is the prime consideration in rotating machinery (Fig. 4), and the superiority of titanium relative to steel and nickel has provided the major motivation for its development in aerospace applications. The potential benefits of silicon nitride, silicon carbide, and carbon – carbon composites over nickel superalloys are considerable if the current major problems–lack of defect tolerance and oxidation resistance–can be resolved. The relative capabilities of materials used in unstressed applications such as furnace heating elements and low-density fibrous insulation are shown in Figure 5.

Applications at temperatures > 1350 °C can be satisfied only by refractory metals and nonmetallic materials (Figs. 3, 4, 5). The high den-

Figure 3. Strength – temperature regimes of high-temperature materials

Figure 4. Specific strength – temperature capability
∗ c/c: Carbon – carbon composites

Figure 5. Material temperature capabilities in unstressed applications

sity and fundamental oxidation problem of refractory metals seriously limit their wider application and further justify the recent increased interest in the use of high-temperature ceramic materials.

2. Factors Influencing Temperature Capability

2.1. Melting Temperature

The *melting temperature* of a material is a major indicator in its usefulness at high temperature.

The theory of atomic structure is well documented [11]. *Ionic bonds* can be strong, particularly with multivalent ions as in MgO. *Covalently bonded* diamond is the hardest material in nature and melts at ca. 3700 °C. *Metallic bonds* can also give rise to high melting points (e.g., 3410 °C for tungsten). Mixed bond types are common; refractory metal carbides and nitrides possess a combination of covalent and metallic bonds.

All bonds assume the most stable electron configuration attainable when the two bonding atoms are brought together. The interatomic bonding forces are influenced by many factors including crystal structure, number of close neighbors (coordination number), bond type, and number of electrons involved per atom. The stronger the attraction or bonding force between two atoms, the smaller is the interatomic distance and the higher the melting point. The variation of melting point with interatomic distance is depicted in Figure 6. Refractory metals, including tungsten, tantalum, molybdenum, and niobium, display the highest metallic melting points. The melting points of the carbides and oxides do not follow the same order as that of the metals themselves because of the modified bonding involved in compound formation (Table 2).

Table 2. Melting points of high-temperature, nonmetallic materials

Material	*mp*, °C
HfC	3890
TaC	3880
ZrC	3530
NbC	3500
WC	2870
SiC	2400 *
ThO_2	3300
HfO_2	2900
MgO	2800
ZrO_2	2680
Al_2O_3	2050
Si_3N_4	1850 *

* Sublimes.

2.2. Volatility

Some materials with a high melting point have a significant vapor pressure (volatility) at elevated temperature, which can limit their high-temperature capability. For example, MgO melts at 2800 °C but exhibits appreciable volatility at 1600 °C; tungsten melts at 3410 °C but suffers ca. 1 % loss in weight, due to evaporation, in

Figure 6. Interatomic distance and melting points of elements as a function of atomic number

100 h at 2560 °C; chromium melts at 1890 °C but experiences 1 % loss in weight at 895 °C [12]. For most materials other than oxides in an oxidizing environment, oxidation or other forms of corrosion impose a lower temperature limit than does volatility.

2.3. Crystal Structure

The majority of useful engineering materials have a cubic crystal system. Examples include most of the common metals and some of the simpler ceramics such as MgO and TiC. Most ceramic materials have a relatively complex crystal structure. The type of crystal structure has a major influence on plastic deformation and diffusion characteristics, which in turn influence zero-time and real-time deformation behavior and, consequently, temperature capability. Zero-time deformation deals with instantaneous behavior when a load is applied; real-time deformation is concerned with time-dependent processes such as creep and fatigue.

2.4. Zero-Time Deformation

The major mechanism involved in zero-time deformation of metals is slip, the relative movement of one crystal plane over another by a process involving the movement of crystal imperfections known as dislocations [13]. Slip occurs more readily along some crystal directions and planes than along others, and the number of slip

systems depends on the crystal structure. Slip is beneficial because it allows metals to be forged into shape and allows stress redistribution to occur in regions of local stress concentration during service. In metallic systems, however, mechanisms that make slip more difficult must be found in order to increase strength and temperature capability.

2.5. Creep

Creep is essentially a slow, continuous real-time deformation at high temperature under stress. It normally occurs at a temperature that is high relative to the melting point of the material, generally at 0.3 – 0.4 T_m for metals and at 0.4 – 0.5 T_m for ceramics, where T_m is the absolute melting point. Mechanisms that strengthen zero-time deformation can also increase the temperature at which creep becomes a limiting factor so that some aluminum alloys can be used under stresses up to 0.5 T_m and nickel superalloys up to 0.7 T_m (see Sections 3.1.1, 3.1.2, and 3.1.4). The precise relationship between creep strain and time depends on temperature, stress, and other factors but generally takes the form shown in Figure 7.

Figure 7. Generalized effects of stress and temperature on creep behavior
a) High stress or high temperature; b) Low stress or low temperature

The creep rate first decreases for a relatively short period of time (stage 1). Steady-state creep then occurs over an extended time period (stage 2) until an acceleration of creep rate (stage 3) is followed by fracture. At low temperature (curve b), the creep strain is restricted because microstructural features (e.g., grain boundaries, precipitates) impede dislocation movement. At higher temperature (curve a), the dislocations can climb out of their blocked slip plane and continue the creep process. The dislocation climb takes place by diffusion, and for many crystalline solids the activation energies for creep and self-diffusion are similar (Fig. 8) [14].

Figure 8. Relationship between activation energies Q for creep and self-diffusion
